Local pollution

ABSTRACT

This paper uses fare changes in Mexico City, Guadalajara, and Monterrey to estimate the price elasticity of demand for urban rail transit. In two of the cases there is a significant fare increase (30%+), and in the third there is a 60-day fare holiday. Ridership responds sharply in the expected direction in all three cities, implying price elasticities which range across cities from -0.23 to -0.32 . In addition, there is suggestive evidence that the temporary fare holiday led to a higher baseline level of ridership. These estimates are directly relevant for policymakers considering alternative pricing structures for urban rail. The paper discusses the relevant economic considerations and then shows how the estimated elasticities can be used to perform policy counterfactuals.

1. Introduction

Worldwide 55% of people live in cities, with this expected to increase to two-thirds by 2050 (United Nations, 2018a). Cities offer significant advantages including educational opportunities, access to labor markets, and rich amenities (Glaeser, 2011). But cities come with their own challenges as well, many closely related to mobility including traffic congestion and local pollution (Zheng and Kahn, 2013).

Public transportation has the potential to ameliorate several of these challenges, making cities greener and more mobile. A recent flurry of empirical studies of transit strikes finds that public transportation is even more effective than previously believed (Anderson, 2014; Adler and van Ommeren, 2016; Bauernschuster et al., 2017). For example, Anderson (2014) shows that traffic congestion increased 47% during a transit strike in Los Angeles.

Another set of studies assesses economic impacts by looking at openings of urban rail lines and other forms of public transportation (Baum-Snow and Kahn, 2000; Baum-Snow et al., 2005; Chen and Whalley, 2012; Gonzalez-Navarro and Turner, 2018; Tsivanidis, 2018; Gupta et al., 2020; Zárate, 2019). Baum-Snow and Kahn (2000), for instance, shows that urban rail expansions during the 1980s in Boston, Atlanta, Chicago, Portland, and Washington DC, led to increased ridership and higher housing prices.

In contrast to these active research areas, relatively little attention has been paid to the operation of existing public transportation systems. In particular, there is surprisingly little recent evidence on the price elasticity of demand for public transportation. This lack of evidence is especially striking compared to the immense number of existing studies on the price elasticity of demand for *private* transportation. See, e.g. Levin et al. (2017) and references therein.

[☆] I am grateful to Severin Borenstein, Gabriel Kreindler, and Eva Lyubich, as well as to the editor (Matthew Freedman) and two anonymous referees for helpful comments. I have not received any financial compensation for this project nor do I have any financial relationships that relate to this research.

For reviews of the older literature on demand for public transportation see [Lago et al. \(1981\)](#), [Cervero \(1990\)](#) and [Goodwin \(1992\)](#). Many of the older studies are not published in peer-reviewed journals and use a variety of different research designs of varying credibility. Not coincidentally, the range of estimates in the existing literature is implausibly large, including everything from zero to well above one ([Holmgren, 2007](#)).

Moreover, there is virtually no existing evidence from low- or middle-income countries. Most population growth and urbanization worldwide over the next few decades is expected to occur in low- and middle-income countries ([United Nations, 2018a](#)), and this is where some of the most significant challenges exist for traffic congestion and local pollution ([World Health Organization, 2016](#)). Consequently, understanding demand for public transportation in these contexts is particularly important.

This study uses fare changes to estimate the price elasticity of demand for urban rail transit in Mexico. Urban rail transit is especially interesting to study compared to other forms of public transportation because of its large scale and low marginal cost. In addition, Mexico is a compelling setting because of its increasing urbanization and rapid growth in vehicle ownership.

The paper exploits three natural experiments, one each in Mexico City, Guadalajara, and Monterrey. In all three cases there is a significant fare change (larger than 30%), and the study uses data on urban rail ridership and a regression discontinuity (RD) research design to measure the change in ridership and implied price elasticity. RD is a natural empirical approach in this context, but has not been used in previous studies.

The analysis shows that ridership responds to price changes in the expected direction in all three cities. When the price for the Mexico City metro increased 67% (from 3 pesos to 5 pesos), ridership fell by 12%. Similarly, when the price for the Guadalajara light rail system increased 36%, ridership fell by 9%. Finally, when the Monterrey metro was offered free of charge for 60 days, ridership increased 61%.

The implied price elasticities are -0.25 , -0.32 , and -0.23 for Mexico City, Guadalajara, and Monterrey, respectively. The preferred specification controls for a cubic polynomial in time as well as month-of-year fixed effects and retail gasoline prices. Estimates are similar with shorter and longer bandwidths, alternative polynomials, alternative controls, and in specifications excluding observations immediately around the fare change. In addition, the paper tests for asymmetric behavior at the beginning and end of the Monterrey fare holiday, finding suggestive evidence that the decrease at the end of the holiday was smaller than the increase at the beginning.

These estimates are directly relevant for policymakers considering alternative pricing structures for urban rail. Policymakers in Monterrey, for example, are considering increasing prices to pay for growing operating costs. Policymakers elsewhere are considering decreasing prices or even moving to fare-free transit.¹ The paper discusses the relevant economic considerations and then shows how the estimated elasticities can be combined with the framework from [Parry and Small \(2009\)](#) and [Parry and Timilsina \(2010\)](#) to perform policy counterfactuals.

The paper proceeds as follows. Section 2 motivates the analysis with information about urban growth and vehicle ownership in Mexico, and then describes the fare changes in Mexico City, Guadalajara, and Monterrey. Section 3 presents the results in graphical and regression form, including results from alternative specifications. Section 4 discusses optimal pricing for public transportation and performs a policy counterfactual. Section 5 concludes.

Table 1
Urban growth and vehicle ownership.

	2000	2018	Growth (%)
Population (Millions)			
Mexico City	18.4	21.5	17%
Guadalajara	3.7	5.0	35%
Monterrey	3.4	4.7	38%
Registered Vehicles (Millions)			
Mexico City	2.5	5.8	132%
Guadalajara	0.3	0.6	103%
Monterrey	0.2	0.5	104%

Note: Population data come from [United Nations \(2018b\)](#). Registered vehicle data come from the Mexican Statistics Institute (*INEGI*), <https://www.inegi.org.mx/programas/vehiculosmotor/>.

2. Background

2.1. Urban growth and vehicle ownership

Like many middle-income countries, Mexico is experiencing rapid urbanization ([United Nations, 2018a](#)). Mexico City, Guadalajara, and Monterrey have all experienced significant population growth since 2000. As incomes have risen over the last two decades, so has vehicle ownership. The number of registered vehicles in all three urban areas has more than doubled since 2000. See [Table 1](#) for population and vehicle registration statistics. This rapid growth in private vehicles helps explain why Mexico City, for example, has some of the worst traffic congestion in the world.²

There has been little attempt in Mexico to price the externalities from driving. Mexico no longer subsidizes gasoline to the degree that it did in previous decades, but gasoline is still inexpensive by international standards. There is no price on carbon dioxide, no price on local pollutants, and no price on traffic congestion. Nor has there been much attempt to encourage carpooling through high-occupancy vehicle lanes ([Hanna et al., 2017](#)). Instead, the country has long attempted to address these externalities using driving restrictions ([Davis, 2008](#); [Gallego et al., 2013](#)) and vehicle emissions testing ([Oliva, 2015](#)).

2.2. Mexico city

Mexico City’s metro is the second largest subway system in North America after New York City, and ninth largest in the world ([UITP, 2018](#)). Daily ridership exceeds 4 million trips. The event of interest occurred December 13, 2013, when the price for the Mexico City metro increased from 3 pesos to 5 pesos, a 67% increase. The exchange rate in December 2013 was 12.8 pesos per dollar, so this is an increase from \$0.23 to \$0.39 per trip.

The price increase was announced on December 7, 2013 by Joel Ortega Cuevas, the managing director of the Mexico City metro.³ The change was made to “guarantee continuity in the provision of service under conditions of safety, meet the requirements of rehabilitation, update and maintain the rolling stock and fixed facilities, and to cover operating and administrative expenses.”⁴

The price structure for the Mexico City metro is very simple. There is a single ticket which allows the rider to go anywhere in the system

² See, e.g., the Tom Tom Traffic Index, https://www.tomtom.com/en_gb/traffic-index/mexico-city-traffic/. Mexico City ranks number 13 worldwide in the most recent index.

³ “El Boleto del Metro Sube a 5 Pesos,” *Expansión*, December 7, 2013, <https://expansion.mx/economia/2013/12/06/el-boleto-del-metro-sube-a-5-pesos>.

⁴ See *Gaceta Oficial Del Distrito Federal*, December 7, 2013, Number 1750. This document outlines specific investments including repairing trains, replacing escalators, and modernizing turnstiles.

regardless of distance. The same ticket is used peak- and off-peak, and during all days of the week. This lack of differentiation is difficult to justify from an economic efficiency perspective but from a study design perspective makes analysis and interpretation particularly straightforward.

Another simplifying feature of all three urban rail systems considered in the analysis is that the great majority of riders pay the standard fare and not some type of discounted multi-trip ticket or monthly- or annual-fixed charge. One of the challenges in previous studies is that prices for different fare categories often change simultaneously and by varying amounts, making results difficult to interpret (see, e.g. Miller and Savage, 2017). On the Mexico City metro, discounted fares are available for the elderly, children under 5 and some other vulnerable groups, but this represents a small share of total ridership.

2.3. Guadalajara

Guadalajara's light rail system (*Tren ligero de Guadalajara*) is the third-largest urban rail system in Mexico, with daily ridership exceeding 250,000 trips. The total size of the system in kilometers, number of trains, and total ridership are all about one order of magnitude smaller than the Mexico City subway. See Appendix Figs. 1–3 for descriptive information about all three rail systems.

Guadalajara's light rail system runs underground only in the city center, and otherwise runs at grade. Mexico City and Monterrey also have a combination of underground and at grade segments, but with a higher proportion underground. For this reason, the paper tends to use the more general "urban rail transit" rather than "subway" when referring to Guadalajara.

The event of interest for Guadalajara occurred on July 27, 2019. On this day the price for Guadalajara's light rail system was increased from 7 pesos to 9.5 pesos. The exchange rate in July 2019 was 19.0 pesos per dollar, so this is an increase from \$0.37 to \$0.50 per trip. As with the Mexico City metro, Guadalajara's light rail system uses a simple ticket that does not differentiate by time-of-day, day-of-week, or destination. Children and elderly receive a 50% discount but all others pay this same standard fare.

The price increase was announced by the governor of the state of Jalisco, Enrique Alfaro Ramírez, days before the increase took place.⁵ According to the governor, the price increase "should have been made years ago", and was needed to "avoid financial collapse".⁶

A challenge with Guadalajara is that the price change occurred relatively recently, so there is less post-event data available. Moreover, data from after March 2020 is excluded from all three cities to avoid the sharp decline in ridership due to Covid-19. For Guadalajara, this leaves only 7 months of data post-event. This ends up being enough for estimating the price elasticity, but is a considerably shorter post-period than is available for the other two cities.

2.4. Monterrey

The Monterrey metro, generally referred to as *Metrorrey*, is the second-largest in Mexico. The metro has two lines with a third line scheduled to open early 2021. There are 35 total stations and average daily ridership is almost 500,000 trips.

⁵ See "Tren Ligero, Macrobus y Rutas Alimentadoras Cobrarán \$9.50", *El Milenio*, July 24, 2019 <https://www.milenio.com/politica/comunidad/aumenta-tarifa-tren-ligero-macrobus-alimentadoras-guadalajara> and "Aumenta 36% El Precio del Tren Ligero y Macrobus en Jalisco", *La Izquierda Diario Jalisco*, July 25, 2019 <http://www.laizquierdadiario.mx/Aumenta-36-el-precio-del-Tren-Ligero-y-Macrobus-en-Jalisco>.

⁶ "Gobernador de Jalisco Justifica Alza de Tarifa en Transporte Público" *Animal Político*, July 29, 2019 <https://www.animalpolitico.com/2019/07/gobierno-jalisco-justifica-aumento-tarifa-transporte/>.

The event of interest for Monterrey occurred during the summer of 2009. During a 60-day period between May 16 and July 14, the Monterrey metro was free. Except for that 60 day period, the Monterrey metro otherwise has a price of 4.5 pesos. The exchange rate in June 2009 was 13.2 pesos per dollar, so at the time of the fare holiday the regular price was \$0.34 per trip.

The fare holiday was announced with little advance warning by the governor of the state of Nuevo Leon, José Natividad González. The price change was implemented to "alleviate a little the economic crisis among the population" and was done along with a temporary reduction in water prices.⁷ Elections were held in Nuevo Leon on July 5, 2009, so the subsidies may have also been politically motivated.⁸

As with Mexico City and Guadalajara, the Monterrey metro uses a simple ticket that does not differentiate by time-of-day day-of-week, or destination. Multi-trip discounts are available for the Monterrey metro, but offer only a modest discount, for example, 6 trips can be purchased for 24 pesos (4 pesos each). In late 2018 the government of Nuevo Leon discussed increasing the price to as high as 9 pesos, but as of 2020 the price remains 4.5 pesos.⁹

3. Data and results

3.1. Ridership data

Fig. 1 plots raw ridership data from all three urban rail systems. These data come from the Mexican Statistics Institute (*INEGI*), which in turn, collects ridership data from the individual urban rail systems. Data after March 2020 are excluded to avoid the sharp decline in ridership due to Covid-19. Data are also excluded from September 2017 for Mexico City because of much lower ridership in this month due to an earthquake which damaged several subway lines.

Fare changes are indicated with vertical lines. As expected, ridership falls in Mexico City in December 2013 when the fare increases. Ridership also falls in Guadalajara in July 2019, when the fare increases, though this change is less noticeable. Finally, in Monterrey the 60-day fare holiday is indicated using two vertical lines. As expected, ridership increases sharply during the holiday period.

Narrowing the windows brings the events into sharper focus. See Fig. 2. The changes in ridership become clearer, particularly for Mexico City and Monterrey. For Monterrey the figure also reveals an earlier ridership increase seven months before the fare holiday in October 2008. This corresponds to the month of inauguration for four new subway stations.¹⁰ As is shown later, controlling explicitly for this expansion has little effect on the estimates.

There is seasonal variation in ridership for all three systems, peaking in the summer and fall. Accordingly, the preferred estimates in the following section include month-of-year fixed effects. The month-of-year fixed effects have little impact on the estimates for Mexico City or Monterrey, but the decline in Guadalajara becomes sharper (and larger) after including month-of-year fixed effects. Ridership is highly seasonal in Guadalajara, with higher levels in August, September, and October, but these higher levels were considerably more muted in 2019 after the price increase.

¹⁰ See "History of Monterrey Metro" *Historia del Sistema de Transporte Colectivo Metrorrey*, http://www.nl.gob.mx/?P=metrorrey_principal.

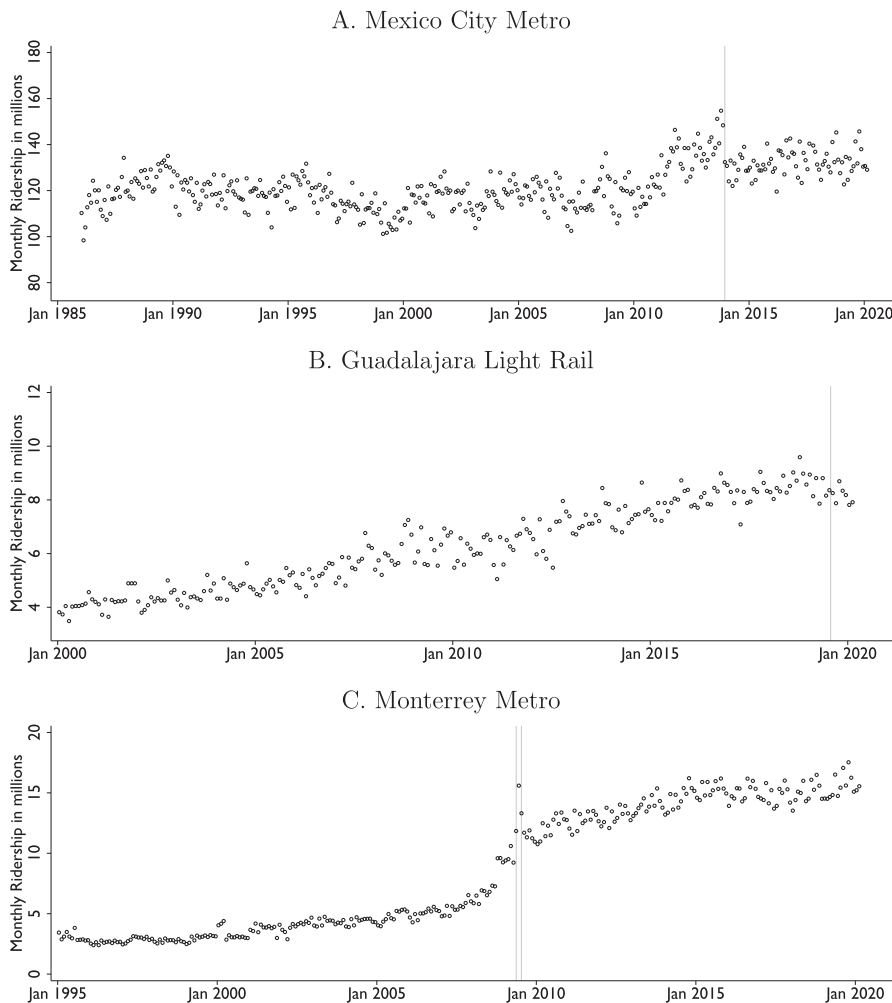

Fig. 1. Monthly ridership in millions.

3.2. Regression Discontinuity Analysis

Fig. 3 overlays a cubic polynomial with a discontinuous break at the time of each event. Three separate regressions were estimated of the following form,

$$ridership_t = \gamma_0 + \gamma_1 1(Change_t) + f(D_t) + \gamma_2 X_t + u_t. \tag{1}$$

The outcome variable $ridership_t$ is ridership in month t . The explanatory variable of interest is $1(Change_t)$, an indicator variable for observations after the price change.¹¹ Specifications also include $f(D_t)$, a third-order polynomial in the time.

Estimates in the tables below come from regressions with additional controls X_t , including month-of-year fixed effects and retail gasoline prices. There are no major changes in retail gasoline prices around the

fare change events. See Appendix Fig. 4.¹² Nonetheless, gasoline prices are included in all regressions as previous research has shown substitution toward public transportation during periods of high gasoline prices (Nowak and Savage, 2013).

The RD figures further sharpen the pattern that was already visually discernible in the previous figures. All three cities exhibit changes in ridership in the expected direction. Ridership falls sharply and discontinuously in Mexico City when the price increases. Ridership falls in Guadalajara as well, though the change is harder to see given the pronounced seasonal variation. Finally, ridership in Monterrey jumps up significantly during the fare holiday, and then jumps back down when the fare is reinstated. The shaded areas in the figure represent a 95% confidence interval constructed using Newey-West standard errors with a two-month lag.

3.3. Estimates and standard errors

Table 2 reports estimates and standard errors from the preferred

¹¹ The fare holiday for Monterrey requires a bit of extra explanation. The 60-days fare holiday ran from May 16 until July 14. Thus, $1(Change_t) = 1$ for June 2009, and $1(Change_t) = 0.5$ for May and July 2009 as both months were treated for half the month. All other months are untreated, $1(Change_t) = 0$. Thus, the coefficient γ_1 in the Monterrey regression reflects the change in ridership associated with the price change, just as it does with regressions for the other two cities.

¹² Monthly average retail gasoline prices in Mexico were collected from publicly-available sources. Data up until 2016 were collected from the Mexican Energy Ministry's *Sistema de Información Energética* and data since 2017 were collected from the Mexican Energy Regulator's *Precios Promedio Mensuales por Entidad Federativa de Gasolinas y Diésel*. Retail gasoline prices in Mexico were set administratively for most of this time period, so tend to vary less than gasoline prices elsewhere (Davis et al., 2019).

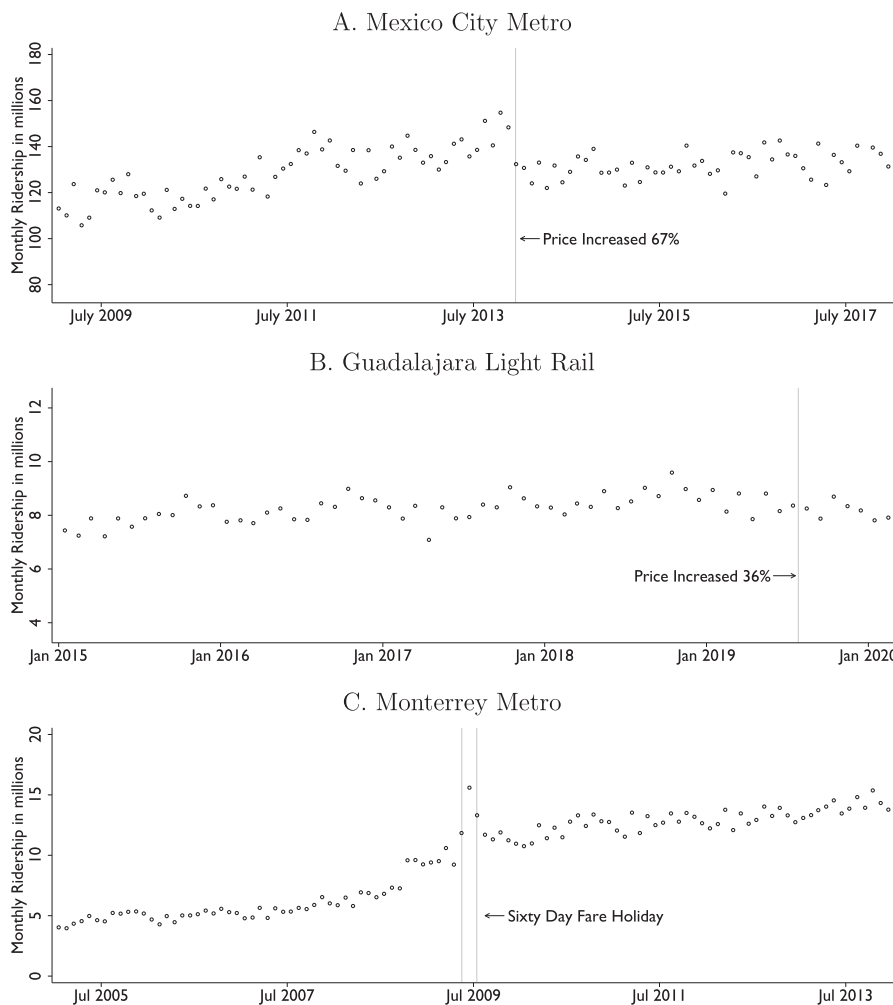

Fig. 2. Monthly ridership, narrower window.

specification. In Mexico City, the 67% price increase resulted in a 12% decrease in ridership. In Guadalajara, the 36% price increase caused ridership to go down by 9%. Finally, in Monterrey, the 100% price decrease resulted in a 61% increase in ridership. The implied price elasticities calculated using the arc method range from -0.23 to -0.32 .

Estimates are similar with alternative bandwidths. See Table 3. Moving across bandwidths some point estimates increase while others decrease, with no consistent pattern. Across all specifications the estimates are statistically significant at the 1% level. The standard errors reported throughout the paper are Newey-West with a two-month lag. A diagnostic test was used to assess the magnitude of serial correlation. The autocorrelation coefficients are statistically significant for two months or less in all three cities, motivating the two-month lag.

Estimates are also similar with alternative polynomials. Table 4 reports estimates for first-, second-, third-, and fourth-order poly-

nomials, as well as for local linear regression.¹³ The cubic polynomial was selected as the baseline specification because it captures the overall pattern of the data without overfitting, but estimates are similar for alternative polynomials as well as for local linear regression. For all cities and specifications the estimates are statistically significant at the 1% level.

Estimates also change little in several additional alternative specifications. Table 5 reports estimates from specifications that do not control for gasoline prices, add controls for rail system characteristics, exclude the first month after the fare change, and exclude one month before and one month after the fare change. Hausman and Rapson (2018) refer to this last specification as estimating a “donut” RD. Estimated elasticities are similar across all specifications, providing reassurance that the results are not driven by gasoline controls, coincident changes in sys-

¹³ Higher-order polynomials are avoided following the recommendations from Gelman and Imbens (2019). Hausman and Rapson (2018) point out that this type of “Regression Discontinuity in Time” (RDiT) has several challenges relative to the standard “cross-sectional RD”. At least in theory, with cross-sectional RD the sample size can be increased by increasing the number of cross-sectional units. However, with RDiT increasing the sample size necessarily entails relying on observations farther away from the threshold. Even with flexible parametric controls, these farther away observations raise concerns about omitted variables bias. Hausman and Rapson (2018) recommend plotting the raw data along with the various polynomials and presenting results for alternative specifications. See Appendix Figs. 5, 6, and 7 for RD plots with alternative polynomials.

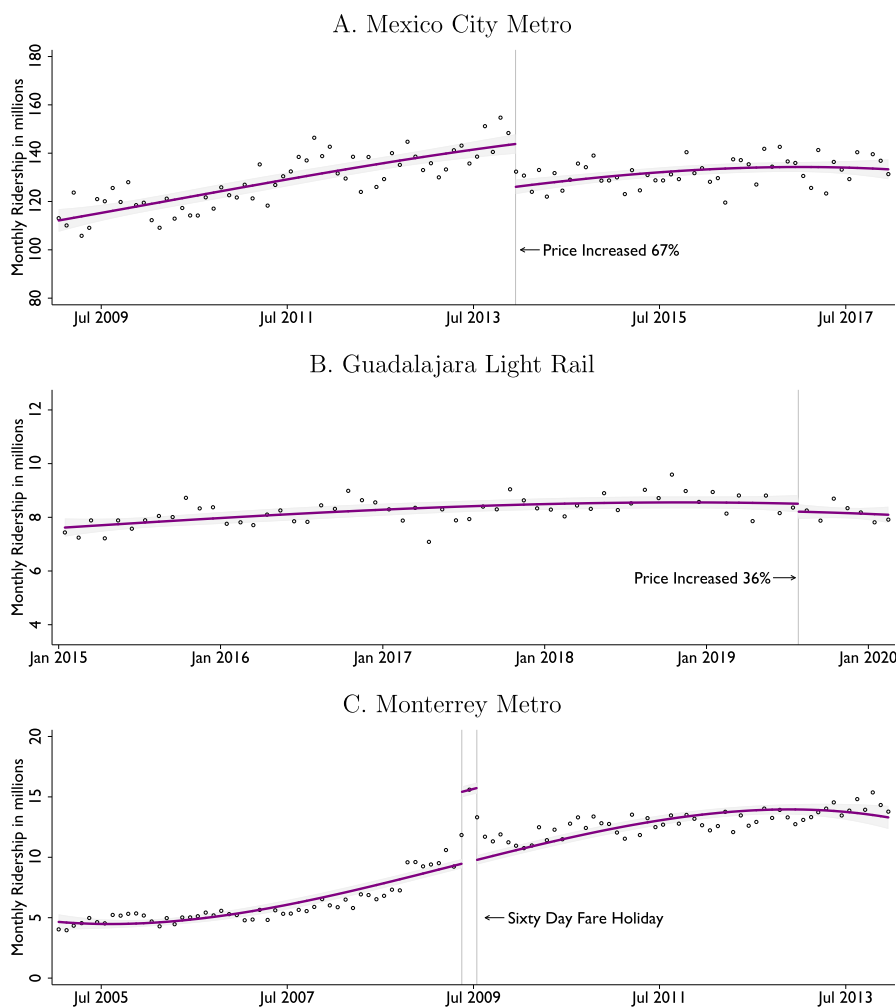

Fig. 3. Regression discontinuity analysis.

tem characteristics, very short-run behavioral responses, or anticipation effects.

In addition to reporting results for these alternative specifications, an attempt was made to rule out additional potential confounding factors. In particular, one might have been concerned about coincident changes to other modes of public transportation. While Mexico City's Bus Rapid Transit system (Metrobús) and some of the other systems expanded considerably during the 2000s and 2010s (Bel and Holst, 2018), there were no sharp changes that coincide with the fare changes considered here.

These estimates are smaller than most estimates in the previous literature. For example, McFadden (1974) estimates a price elasticity for Bay Area Rapid Transit (BART) of -0.86 , using survey data from 213 respondents and a conditional choice model. Holmgren (2007) finds using a meta-analysis a price elasticity of -0.59 for the United States, Canada, and Australia, and -0.75 for Western Europe. Despite rapid growth, private vehicle ownership in Mexico remains less common than in these higher-income settings, so the lower price elasticities may reflect reduced scope for substitution to private vehicles.

It would have also been interesting to attempt to measure cross-price elasticities, or to attempt to measure the effect of these price changes on air quality or traffic congestion. However, one would expect these secondary effects to be relatively small in magnitude and difficult to distinguish empirically from naturally occurring month-to-month variation. In addition, the available ridership data for buses and other forms of public transportation tend to be less systematically collected and not as reliable as the data for urban rail.

3.4. Persistence

The ridership changes appear persistent. In Mexico City, ridership peaks prior to the price increase in 2013, but then never again regains that same level of ridership. In Guadalajara, the decrease in ridership is persistent throughout the seven months for which data are available. Finally, higher ridership levels persist in Monterrey throughout the fare holiday. One might have expected ridership to fall in Monterrey after an initial burst of ridership, for example, due to the novelty of the free fare, but, if anything, ridership actually appears to continue increasing throughout the 60 days.

There is suggestive evidence that the fare holiday in Monterrey led to a higher baseline level of ridership. Fig. 3 and the regression estimates in Tables 2, 3, 4 and 5 impose a symmetric response to the holiday, with equal changes in ridership at the beginning and end of the holiday. However, when these changes are allowed to be asymmetric, the decrease at the end of the holiday is smaller than the increase at the beginning. See Appendix Fig. 8 and Appendix Table 1. Although the difference is not statistically significant (p -value 0.28), this is consistent with new riders learning more about the metro because of the fare holiday and then sticking with it even after the fare holiday has ended.¹⁴

¹⁴ In related work, Larcom et al. (2017) find that a significant fraction of commuters on the London subway make persistent changes in routes following a strike which forced experimentation.

Table 2
The effect of price changes on urban rail transit.

Mexico City	Guadalajara	Monterrey
A. Price Change, In Percent		
+67%	+36%	-100%
B. Ridership Change, In Percent		
-12%	-9%	+61%
(1.5)	(2.5)	(4.6)
C. Implied Price Elasticity		
-.25	-.32	-.23
(.03)	(.09)	(.01)
$n = 107$	$n = 62$	$n = 108$
$r^2 = 0.80$	$r^2 = 0.84$	$r^2 = 0.97$

Note: This table reports coefficients and standard errors from three separate regressions. In all regressions the outcome variable is monthly total ridership and the explanatory variable of interest is an indicator variable equal to one for observations after the fare change. All regressions control for a third-order polynomial in time, month-of-year fixed effects, and average retail gasoline prices. Ridership changes are reported in percent relative to the ridership level just prior to the price change. Implied elasticities are calculated using the arc method. Standard errors are Newey-West with a two-month lag.

Thus the evidence from all three cities points to persistent, not transitory changes in behavior. That said, it is important to emphasize that the RD design measures short-run, not long-run price elasticities. The coefficient of interest, γ_1 is identified using the immediate change in ridership coincident with fare adjustments, so does not capture longer-run adaptations such as changes in where people live or work. The previous literature has tended to find somewhat larger long-run price elasticities, e.g. about 25% larger in the meta-analysis by [Holmgren \(2007\)](#), though these longer-run impacts are more difficult to credibly identify as it becomes challenging to disentangle the causal effect of price changes from omitted variables and broader trends.

4. Economic implications

The estimates from the previous section provide some of the information about demand behavior necessary to evaluate the economic costs and benefits from alternative fares for urban rail transit. This section discusses the relevant economic considerations, leaning heavily on the framework and parameters from [Parry and Small \(2009\)](#) and [Parry and Timilsina \(2010\)](#). The section then illustrates how the estimated elasticities can be used to perform policy counterfactuals. The section focuses on the specific counterfactual of setting fares equal to zero, but the exercise could just as easily be repeated for alternative counterfactuals.

4.1. Optimal pricing for public transportation

[Parry and Small \(2009\)](#) and [Parry and Timilsina \(2010\)](#) use a static representative agent model of substitution between rail, bus, and private vehicles to derive optimal subsidies for public transportation. Particularly relevant is [Parry and Timilsina \(2010\)](#) which focuses on the transportation system in Mexico City.

The following equation, adapted from [Parry and Timilsina \(2010\)](#), shows that the optimal price per passenger mile for urban rail transit,

p^{R*} , can be expressed as follows:

$$p^{R*} = \theta^R + E^R + (E^A)\rho_{AR} + (E^B)\rho_{BR}. \quad (2)$$

Here θ^R is the marginal cost per passenger mile of rail travel, and E^R , E^A , and E^B are the unpriced external costs per passenger mile of rail (R), private vehicle (A), and bus (B), respectively. Parameters ρ_{AR} and ρ_{BR} are cross-mode elasticities which describe how changes in rail usage affect passenger miles traveled via private vehicle and bus, respectively.

Thus the first two terms, θ^R and E^R , are the marginal cost and marginal external cost of rail travel. [Parry and Timilsina \(2010\)](#) use $\theta^R = 9.2$ cents and $E^R = 0$, so the marginal social cost of rail travel is 9.2 cents per passenger mile and a typical 5-mile trip would therefore have a marginal social cost of 46 cents.¹⁵ Here and throughout all dollar amounts have been normalized to reflect year 2020 dollars.

The last two terms, $(E^A)\rho_{AR}$ and $(E^B)\rho_{BR}$ quantify substitution away from private vehicles and buses. The analyses by Parry and coauthors incorporate carbon dioxide, air pollution, traffic congestion, and accident externalities. In particular, [Parry and Timilsina \(2010\)](#) assumes $E^A = 29.0$ cents, and $E^B = 14.2$ cents per passenger mile for private vehicles and buses, and that $\rho_{AR} = -0.35$ and $\rho_{BR} = -0.35$, i.e. that 70% of changes in rail travel are diverted equally from private vehicles and buses. The other 30% is assumed to be a change in the overall level of travel, and without externality implications.¹⁶ Multiplying, $(E^A)\rho_{AR} = -10.2$ and $(E^B)\rho_{BR} = -5.0$, so each passenger mile via rail offsets 10.2 cents of damages from private vehicles and 5 cents of damages from buses.¹⁷

Thus [Parry and Timilsina \(2010\)](#) find that these last two negative terms are significantly larger in magnitude than the first two positive terms, i.e the reduced externalities from substitution away from private vehicles and buses more than outweighs the social marginal cost of rail travel. That is, under their assumptions the optimal price for urban rail in Mexico City is negative and equal to -6.0 cents per mile.

[Parry and Timilsina \(2010\)](#) do not perform an analogous exercise for Monterrey or Guadalajara, but external costs are likely to be similar in these other cities. Avoided carbon dioxide emissions are equally valuable anywhere and while Monterrey and Guadalajara have smaller populations, the population densities are roughly comparable.¹⁸ Moreover, the optimal price for Mexico City is sufficiently negative that even if the traffic congestion and local air pollution components were somewhat smaller for Guadalajara and Monterrey the optimal price might still be below zero.

¹⁵ The θ^R was determined assuming that 90% of operating costs are marginal, and that only 10% are fixed costs. This is mostly labor. The pure energy component of marginal cost is quite small. Urban rail is more energy-efficient than road transportation because of 85%+ lower rolling friction losses, fewer stops, and the high performance of electric motors compared to internal combustion engines. For example, [International Energy Agency \(2019\)](#) reports a global average for passenger rail travel of 4 tons of oil equivalent per million passenger kilometers, equivalent to 0.37 kW h per five mile trip, i.e less than 5 cents.

¹⁶ See, in particular, [Table 2](#) and [Section 3.3](#) in [Parry and Timilsina \(2010\)](#). The dollar amounts here have again been normalized to reflect year 2020 dollars. In addition, the external cost for buses reported here is a weighted average over two different forms of bus transit they consider in their model. Also, in the interest of parsimony the equation here assumes that all externalities accrue on a per-mile basis rather than distinguishing between gasoline- and mileage-based externalities.

¹⁷ These calculations could undoubtedly be refined further. For example, [Parry and Timilsina \(2010\)](#) assume a social cost of carbon of \$10 per ton of carbon dioxide whereas recent estimates are considerably higher, for example, \$31 in [Nordhaus \(2017\)](#). This would have relatively little impact on the overall results, however, as local pollution and traffic congestion are far larger components quantitatively.

¹⁸ According to INEGI, *Densidad de población*, Mexico City has a population density of about 6000 people per square kilometer. In contrast, the municipalities of Monterrey and Guadalajara have population densities of 3400 and 9600 people per square kilometer, respectively.

Table 3
Estimated price elasticities, alternative bandwidths.

	Baseline Specification (1)	Longer Bandwidth (2)	Shorter Bandwidth (3)	Even Shorter Bandwidth (4)
Mexico City	-.25 (.03)	-.27 (.03)	-.19 (.05)	-.23 (.05)
Guadalajara	-.32 (.09)	-.28 (.09)	-.28 (.09)	-.23 (.06)
Monterrey	-.23 (.01)	-.23 (.01)	-.24 (.01)	-.23 (.01)

Note: This table reports coefficients and standard errors from twelve separate regressions. The baseline specification is identical to the estimates in Table 2 and uses an eight-year bandwidth, four years on either side of the fare change. The longer bandwidth includes five years on either side of the fare change. The shorter bandwidth includes three years on either side of the fare change, while the even shorter bandwidth includes two years on either side of the fare change. All specifications include a third-order polynomial in time, month-of-year fixed effects, and average retail gasoline prices. For Guadalajara in all specifications there are only 7 months after the fare change as observations after March 2020 are dropped to exclude the period affected by Covid-19. Implied elasticities are calculated using the arc method. Standard errors are Newey-West with a two-month lag.

Table 4
Estimated price elasticities, alternative polynomials.

	Linear (1)	Quadratic (2)	Cubic (3)	Quartic (4)	Local Linear (5)
Mexico City	-.26 (.03)	-.22 (.02)	-.25 (.03)	-.22 (.03)	-.26 (.03)
Guadalajara	-.33 (.04)	-.27 (.08)	-.32 (.09)	-.25 (.09)	-.28 (.09)
Monterrey	-.23 (.02)	-.22 (.02)	-.23 (.01)	-.23 (.01)	-.25 (.01)

Note: This table reports coefficients and standard errors from fifteen separate regressions. The baseline specification is the third-order polynomial in column (3), identical to the estimates in Table 2. Columns (1), (2), and (4) use first-, second-, and fourth-order polynomials, respectively. Columns (1–4) use an eight-year bandwidth, four years on either side of the fare change. Column (5) reports estimates using local linear regression with a uniform kernel and an optimal bandwidth selected following Imbens and Kalyanaraman (2012). All specifications include month-of-year fixed effects and average retail gasoline prices. For Guadalajara in all specifications there are only 7 months after the fare change as observations after March 2020 are dropped to exclude the period affected by Covid-19. Implied elasticities are calculated using the arc method. Standard errors are Newey-West with a two-month lag.

4.2. Additional considerations

Negative prices are impractical for public transportation because they would invite professional “riders”. But the results from Parry and Small (2009) and Parry and Timilsina (2010) do suggest that lower, or perhaps even zero fares for urban rail transit could make sense in some circumstances. Accordingly, Section 4.3 considers the policy counterfactual of fare-free travel. However, before this exercise, there are several additional economic considerations that should be discussed. To fully quantify these other factors goes well beyond this current analysis but it is nonetheless valuable to briefly outline the broader issues.

First, it is worth emphasizing that this is a second best policy environment. In particular, equation (2) assumes that the externalities from other transport modes are not already priced. This is an appropriate assumption in many contexts including Mexico, but is nonetheless worth highlighting. The broader point that there is substitutability between taxes on private vehicles and transit subsidies is made by Basso and Silva (2014).

It is also important to point out that the optimal price derived in Section 4.1 ignores crowding externalities (Kraus, 1991). Off-peak urban rail systems can absorb additional riders, either because current trains have excess capacity or because additional trains can be added. However, during peak travel, additional riders impose negative externalities, forcing riders to stand or to be uncomfortable, or to have to wait for a second train (Hörcher et al., 2017). De Palma et al. (2017)

explore how crowding externalities can be mitigated through capacity investments and dynamic pricing. The natural response would be to charge a “congestion” price during peak hours (Vickrey, 1955, 1963).

Working against these crowding externalities are scale economies. Economists have long recognized that public transportation is an increasing returns-to-scale technology. The more riders in the system, the shorter the wait times for all riders (Mohring, 1972). Parry and Timilsina (2010) abstract from both crowding externalities and scale economies, while Parry and Small (2009) essentially assume that these two factors balance each other out, with the transit agency optimizing over the number of trains, size of trains, and load factor. But of course some systems have capacity constraints that make such optimization impossible during some hours in which case the optimal fare during peak periods would be much higher.

A more comprehensive analysis would also consider equity. The discussion and analysis throughout focuses on economic efficiency and ignores distributional considerations. It is worth highlighting, however, that the fare changes considered in this analysis are large enough to matter from a distributional perspective. For example, the minimum daily salary in Mexico City in 2013 was 65 pesos.¹⁹ Thus when the price

C. Adding Controls for Rail System Characteristics			
	-.25	-.34	-.20
	(.04)	(.08)	(.01)
D. Excluding First Month After Fare Change			
	-.26	-.34	-.25
	(.03)	(.10)	(.01)
E. Excluding One Month Before and One Month After Fare Change			
	-.25	-.37	-.25
	(.04)	(.11)	(.01)

Note: This table reports coefficients and standard errors from fifteen separate regressions. In all regressions the outcome variable is monthly total ridership and the explanatory variable of interest is an indicator variable equal to one for observations after the fare change. Unless otherwise stated, all regressions control for a third-order polynomial in time, month-of-year fixed effects, and average retail gasoline prices. Panel C adds linear controls for the number of trains, total system length, and total kilometers traveled. Implied elasticities are calculated using the arc method. Standard errors are Newey-West with a two-month lag.

for the subway increased from 3 pesos to 5 pesos, a worker earning the minimum daily salary who takes two trips per day went from spending 9% (6/65) to 15% (10/65) of their income on public transportation. In Mexican cities it tends to be individuals with below average incomes who use rail transit. Indeed, the availability of public transportation is one of the reasons lower-income households live in cities to begin with (Glaeser et al., 2008), and previous research has shown that transit subsidies are progressive (Basso and Silva, 2014).

4.3. Policy counterfactual

Table 6 describes the policy counterfactual. Specifically, the table uses the estimated price elasticities to quantify the economic costs and benefits of making urban rail transit free in all three cities. These are back-of-the-envelope calculations and should be viewed as illustrative, rather than exact representations.

This exercise relies on the preferred estimates of the price elasticity of demand from Table 2. For these calculations, making urban rail transit free is treated as a 100% decrease in price so the counterfactual quantities are calculated by multiplying current ridership by one plus the elasticity of demand. For example, in Mexico City, annual ridership

increases from 1.6 billion to 2.0 billion ($1.6 * 1.25$) riders per year, an increase of 400 million riders per year. The Guadalajara and Monterrey systems are smaller in scale but experience similar percentage increases in ridership.

The foregone revenue would be substantial. Mexico City, for example, currently collects \$350 million annually from riders, but this revenue would disappear. Consumer surplus of riders would increase by this full amount plus the gain in consumer surplus from the additional trips. Revenue impacts are smaller in scale in Guadalajara and Monterrey, but also substantial. Guadalajara currently charges considerably more per rider so the revenue impacts per rider are proportionately larger.

Operating costs would increase. Based on the assumptions in Parry and Timilsina (2010), the marginal cost per passenger trip is 46 cents. So, for example, an extra 400 million passenger trips in Mexico City would increase operating costs by \$183 million annually. On the other hand, negative externalities would decrease. Following Parry and Timilsina (2010), each trip via urban rail is assumed to reduce traffic congestion, local pollution, and other negative externalities by an amount valued at 76 cents. So, for example, an extra 400 million passenger trips in Mexico City would decrease negative externalities by \$303 million annually.

These calculations rely heavily on the assumptions in Parry and Timilsina (2010). For example, these numbers assume that the most operating costs are marginal, not fixed. If there are economies-of-scale that make it possible to increase ridership without incurring near proportional cost increases, then the cost impacts would be lower. In addition, the framework makes strong assumptions about substitution patterns between transportation modes, as well as about the external costs of traffic congestion and accidents.

These calculations also ignore operational efficiencies from not having to collect fares. With fare-free transit there would be no reason to wait in line, resulting in time savings for riders. In addition, fare-free transit would make gates, turnstiles, electronic ticket kiosks, and other fare collection equipment unnecessary, reducing capital and maintenance expenditures. There would also likely be labor savings, with fewer employees needed at stations and for ticket enforcement.

5. Conclusion

This paper finds that the price elasticity of demand for urban rail transit in Mexico ranges across cities from -0.23 to -0.32 . These estimates come from a regression discontinuity research design that, although novel in this literature, is a natural empirical approach in this context. RD lends itself well to graphical analysis and is transparent and robust, with results in this case varying little across specifications.

Perhaps it is not surprising that demand is relatively inelastic. Transportation is time-intensive, so the pecuniary cost of public transit is only part of the overall cost of travel. As incomes increase so does the value of time, so one would expect price elasticities to become smaller. This pattern has been discussed in the context of private transportation (Hughes et al., 2008), but is likely true for public transportation as well.

These elasticities are directly relevant for evaluating alternative pricing structures. Ridership in urban rail systems around the world

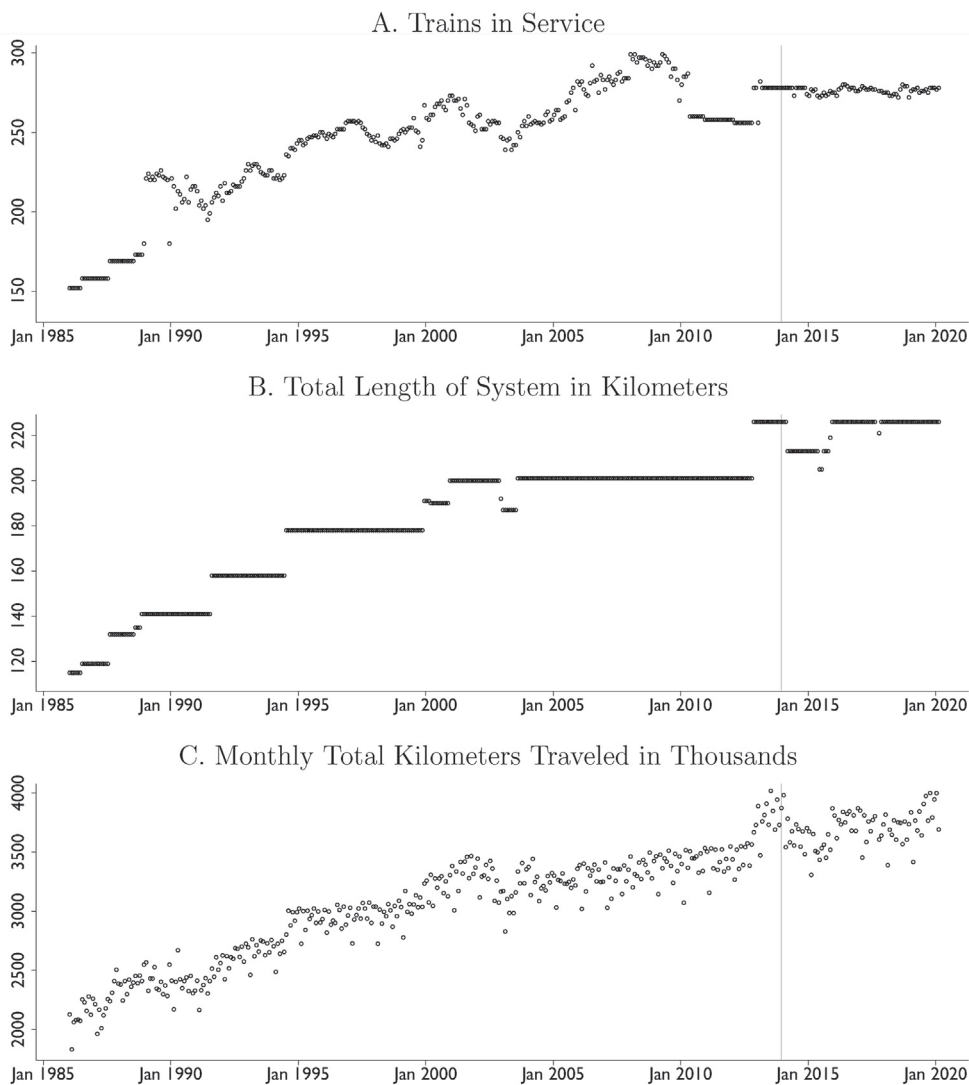

Table 6
Illustrative policy counterfactual.

	Mexico City	Guadalajara	Monterrey
Price Elasticity of Demand	-.25	-.32	-.23
Current Price Per Passenger Trip (one way fare, in dollars)	\$0.22	\$0.43	\$0.20
Current Annual Total Passenger Trips (in 2019, millions)	1595	100	187
Predicted Annual Total Passenger Trips if the price were zero (in millions)	1994	132	230
Annual Foregone Fare Revenue (Millions, USD\$)	\$351	\$43	\$37
Annual Increased Operating Costs (Millions, USD\$)	\$183	\$15	\$20
Annual Reduced Negative Externalities (Millions, USD\$)	\$303	\$24	\$33

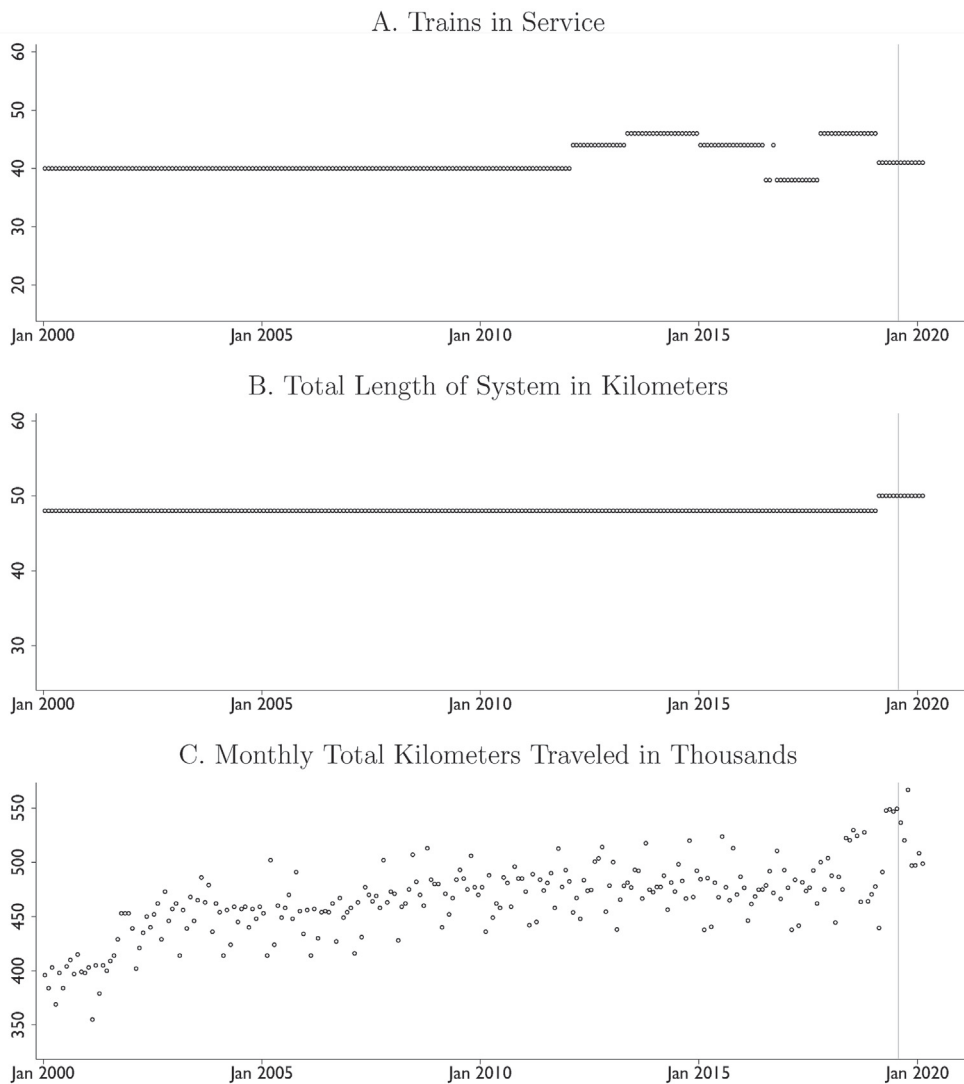

has fallen sharply since March 2020 due to COVID-19. The drop in revenue has put these systems into a budget crisis, forcing many operators to revisit their fare policies and to look for additional government sup-

port. Thus now is a particularly opportune time to think more broadly about pricing public transportation.

	(4.6)	
B. Controlling for October 2018 Expansion		
	+50%	
	(4.0)	
C. Asymmetric Specification		
Increase at Beginning of Fare Holiday	Decrease at End of Fare Holiday	Test of Equality
+64%	-56%	
(6.2)	(4.3)	<i>p</i> -value = 0.28

Note: This table reports the estimated ridership change and standard errors from three separate regressions. Panel A reports results from the baseline specification, identical to the estimates for Monterrey reported in Table 2. Panel B reports results from a specification which includes an indicator for observations after October 2008 when four new stations were inaugurated. Finally, Panel C allows for different changes in ridership at the beginning and end of the fare holiday. Panel C also reports the *p*-value corresponding to a test where the null hypothesis is that the two changes are identical.
