Macroeconomic Order Flows: Explaining Equity and Exchange Rate Returns

Abstract

Macroeconomic models of equity returns perform poorly. The proportion of daily index returns that these models explain is essentially zero. Instead of relying on macroeconomic determinants, our model includes a concept from microstructure - order flow. Order flow is the proximate determinant of price in all microstructure models. We explain aggregate equity returns as well as exchange rates in a model with heterogenous beliefs. Belief changes are shown to be observable through order flow. To test the model we construct daily aggregate order flow data from all equity trades in the U.S. and France from 1999 to 2003. Almost 60 percent of the daily returns in the S&P100 index is explained jointly by exchange rate returns and macroeconomic order flows.
1 Introduction

The aggregate stock market index and the exchange rate are known to have a very low correlation with any other measurable macroeconomic variable (Frankel and Rose (1995), Rogoff (2001)). This motivates us to examine a new financial market variable called order flow in its relationship to stock and exchange rate returns. Order flow is the net of buy minus sell initiated orders. In the forex market, daily exchange rate returns and daily forex order flow show a remarkably high correlation (Evans and Lyons (2002a, 2002b, 2002c)) and even permanent changes in the exchange rate appear to be explained by order flow. Unfortunately, most of the microstructure literature features order flow as an exogenous variable. Its very origin remains unexplained and open to different interpretations.

This paper advances the existing literature in two directions. First, we add microfoundations to the existing literature on order flow. We link the order flow concept to heterogeneous belief changes of investors and therefore allow for a coherent interpretation. It is argued that the portfolio reallocations resulting from belief changes are predominantly pursued through trade initiation. Recent evidence from the microstructure literature (Hollifield et al. (2004)) confirms that the likelihood of trade initiation increases with the magnitude of the deviation between agents’ valuations and the current midprice of a stock. Since order flow represents a summary statistic on the direction of trade initiation, it directly identifies aggregate belief changes. Second, we propose a two country model in which two equity markets and the exchange rate market can be analyzed jointly. The multimarket setting imposes testable restrictions on international market interdependence.

On the empirical side, we show that an extraordinarily high percentage of the daily aggregate equity return variation can be explained jointly by the exchange rate and macroeconomic order flows. For the S&P100 we are able to explain around 60 percent of the daily return variation and for the CAC40 approximately 40 percent. In accordance with theory, the return dynamics in both equity markets does not only depend on the own market order flow, but also significantly on the order flow in the overseas market. This market interdependence appears to be well explained by heterogeneous belief shifts across different investor types. We also show that time varying risk premia defined as the deviations from uncovered equity parity can be well explained by our model. This contrasts with the shortcomings of existing models to account for deviations from uncovered interest parity. Uncovered equity parity (Hau and Rey (2003)) is the analogue to uncovered interest parity in our model.

Heterogeneous beliefs and their change is the focus of our inquiry. Survey data suggests that international differences in equity return beliefs are in fact important. Shiller et al. (1996) document large aggregate differences of opinion on the price expectations of the Nikkei and S&P100 index across Japanese and American fund managers. Hau and Rey (2005) group international fund managers by their location and document large common components with respect to international fund allocations. Such international equity reallocations in turn trigger order flow in the FX market. Belief changes about equity returns therefore also influence the exchange rate return.

Our paper also relates to a recent literature which focuses on the role of order flow in the U.S. equity market. Hasbrouck and Seppi (2001) show that commonality in the order flows of individual stocks explains roughly two-thirds of the commonality in returns. But this paper restricts itself to high frequency intervals. Chordia and Subrahmanyam (2004) study the relationship between order flow and
daily returns of individual stocks. Pastor and Stambaugh (2003) find that market wide liquidity is a state variable important for asset pricing at the daily frequency. Chordia, Roll and Subrahmanyam (2002) document for the period 1988 to 1998 that aggregate order flow in the NYSE is correlated with contemporaneous daily S&P500 returns. But their regressions are not based on any structural model and show much lower explanatory power. To the best of our knowledge, no paper has tried to formally model aggregate equity returns in terms of aggregate equity order flow or related cross country differences in equity order flows to exchange rate movements.

The following section presents the model. Section 3 summarizes and explains the resulting equilibrium relationships. The data is explained in Section 4. Section 5.1 discusses the estimation results for aggregate equity returns and Section 5.2 contain our model estimation for the time varying deviations from uncovered equity parity. Section 6 concludes.

2 The Model

The following section describes a simple multi-market setting in which different types of fund managers experience exogenous belief changes about the fundamental (or terminal) value of home and foreign equity. The model allows us to explore how these belief changes relate to equity and foreign exchange order flows and determine equity and exchange rate returns. We assume four different funds listed in Table 1: An international equity fund, investing in home and foreign equity; an international bond fund, investing in home and foreign bonds; a home country fund, investing in home equity and a home bond and a foreign fund, investing in foreign equity and a foreign bond.\(^1\) Our model therefore features a segmented market in which the exchange rate risk is not diversified.

The bonds in both markets are assumed to be in completely price inelastic supply with a constant return in local currency assumed to be \(r\) for both home and foreign bonds.\(^2\) The bond prices are normalized to 1 without loss of generality. Price determination in both equity markets and the foreign exchange market occurs through a centralized limit order book. The price contingent demand functions are revised once a belief change occurs. We interpret the transaction volume which results from a shift of the demand function as initiated by the trader who experiences the belief shift. Let \(x^H_e\) and \(x^F_e\) denote the home and foreign equity market investment of the international fund, respectively, and \(x^H_h\) and \(x^F_f\) the domestic investments of the home and foreign fund. For simplicity, we assume that there are zero net stocks outstanding. The market clearing condition for the equity markets then takes the form

\[
\begin{align*}
  x^H_e + x^H_h &= 0 \\
  x^F_e + x^F_f &= 0.
\end{align*}
\]

The foreign exchange market clears for a demand \(x^P_e P^P_e\) for foreign balances on the part of the international equity market and a currency demand \(x^P_b B^P_b\) from the international bond fund. Under zero net

\(^1\)We fix notation as follows: the four funds are indicated with the subscripts \(h, f, e\) and \(b\) for home, foreign, international equity and international bond respectively; the superscripts \(H\) and \(F\) refer to holdings of home and foreign equities respectively and the superscripts \(B^H\) and \(B^F\) refer to holdings of home and foreign bonds respectively.

\(^2\)We do not specify what pins down the riskless rate of interest in the model. In addition, there is no distinction between real and nominal returns. The reader may like to think of the riskless rate as being determined by the rate of time preference or a steady state marginal efficiency of capital. Finally, the assumption that the riskless rate is the same in both countries has no bearing on the results.
balances, we have

\[ x^F P^F + x^B P^F = 0 \]

We assume that all four funds are fully leveraged and that their net asset position is zero. In combination with the zero net equity supply, this assumption implies that we can neglect risk premia in the analysis. The exchange rate, \( E \), is defined as the ratio of home (U.S.) to foreign currency (Euro), hence an increase in \( E \) corresponds to a dollar depreciation.

The investment behavior of the four funds is defined by the following assumption:

**Assumption 1: Fund Objectives**

The four investment funds \( i = e, b, h, f \) pursue investment objectives which maximize a CARA objective function given by

\[ U_i = E_i(\Delta \Pi_i | I) - \frac{1}{2} \rho_i Var(\Delta \Pi_i | I) \]

where the expected net payoffs \( E_i(\Delta \Pi_i | I) \) and payoff variance \( Var(\Delta \Pi_i | I) \) are conditional on equity prices and the exchange rate \( I = \{ P^H, P^F, E \} \) and \( \rho_i \) denotes the coefficient of absolute risk aversion.

1. The international equity fund \( (e) \) chooses optimal home and foreign equity holdings \( (x^H_e, x^F_e) \) subject to a budget constraint

\[ 0 = x^H_e P^H + x^F_e E P^F. \]

2. The international bond fund \( (b) \) chooses optimal home and foreign bond holdings \( (x^B_H, x^B_F) \) subject to a budget constraint

\[ 0 = x^B_H E + x^B_F. \]

3. The home fund \( (h) \) chooses optimal home equity and home bond holdings \( (x^H_h, x^B_H) \) subject to the budget constraint

\[ 0 = x^H_h P^H + x^B_H. \]

4. The foreign fund \( (f) \) chooses optimal foreign equity and foreign bond holdings \( (x^F_f, x^B_F) \) subject to the budget constraint

\[ 0 = x^F_f P^F + x^B_F. \]

The mean-variance framework allows for a particularly straightforward closed-form solution. Our main interest is not the steady state solution of the price system, but its reaction to perturbations. In particular, we are interested in the price and order flow effects if each fund manager changes his belief about the fundamental value of equity in a heterogenous manner. We assume a single stochastic belief change around the correct expected liquidation values of equity. Formally, we have:
Assumption 2: Heterogenous Belief Changes

Managers for the funds $i = e, b, h, f$ undergo heterogenous stochastic belief changes $\mu = (\mu_e^H, \mu_e^F, \mu_h^H, \mu_f^F)$ about the liquidation value of home and foreign equity\(^3\). Starting from initially correct beliefs about the steady state liquidation values $(V^H_e, V^F_e)$ of home and foreign equity, the new conditional beliefs $(I = \{P^H, P^F, E\})$ about the fundamental equity value can be expressed as

\[
\begin{align*}
\mathcal{E}_e(V^H | I) &= V^H + \mu_e^H \\
\mathcal{E}_e(V^F | I) &= V^F + \mu_e^F \\
\mathcal{E}_h(V^H | I) &= V^H + \mu_h^H \\
\mathcal{E}_f(V^F | I) &= V^F + \mu_f^F.
\end{align*}
\]

Heterogenous belief changes concern only equity valuation. Relative to bonds with predefined cash flows, equity is notorious difficult to value and might therefore be more exposed to belief changes. These belief changes only concern the first moment. The funds hold identical and correct beliefs concerning the variances. The liquidation value of both the home and foreign equity has a variance $\sigma_e^2$ and the liquidation value of currency a variance $\sigma_E^2$.

3 Equilibrium Relationships

The objective function of each fund is defined in terms of mean and variance of the terminal payoff. This allows for simple linear asset demand functions for each fund. Combined with the market clearing condition for the two equity markets and the forex market, we therefore obtain a linear system of three equations which characterizes the equilibrium prices and returns as a function of the belief changes. The three markets in our model are interrelated in the sense that a belief shock in one market affects the equilibrium price in the other two. For example, a positive belief shock for the home fund manager will increase the price of domestic equity. Higher prices in domestic equity induce a substitution effect on the part of the international equity fund, which will increase its demand for foreign equity and reduce its home country equity holdings. This increases the foreign equity price and at the same time increases the demand for foreign exchange balances. The foreign currency will therefore appreciate.

The equilibrium return impact of general belief change on the part of all equity investors is summarized in Proposition 1:

**Proposition 1: Returns and Heterogenous Beliefs**

The equilibrium returns $R = (R^H, R^F, R^E)$ for home equity, foreign equity, and the exchange rate, respectively are linearly related to belief changes $\mu = (\mu_e^H, \mu_e^F, \mu_h^H, \mu_f^F)$ about the home and the foreign equity value according to

\(^3\)Obviously, holders of the international bond fund do not suffer from misperceptions about equity prices because they never invest in that asset.
AR = B\mu

for matrices A and B defined as

\[
A = \begin{bmatrix}
(1 + \lambda_h) & -1 & -1 \\
-1 & (1 + \lambda_f) & 1 \\
-1 & 1 & (1 + \lambda_b)
\end{bmatrix}, \quad
B = \frac{1}{1+r} \begin{bmatrix}
1 & -1 & \lambda_h & 0 \\
-1 & 1 & 0 & \lambda_f \\
-1 & 1 & 0 & 0
\end{bmatrix}
\]

a riskless rate r, parameters defined as

\[
\lambda_h = \frac{\rho_e \left[2\sigma^2 + (1+r)^2 \sigma_E^2\right]}{\rho_h \sigma^2}, \quad \lambda_f = \frac{\rho_e \left[2\sigma^2 + (1+r)^2 \sigma_E^2\right]}{\rho_f \sigma^2}, \quad \lambda_b = \frac{\rho_e \left[2\sigma^2 + (1+r)^2 \sigma_E^2\right]}{\rho_h (1+r)^2 \sigma_E^2}.
\]

Proof: See Appendix.

The return vector R is uniquely determined by the belief changes \( \mu \) as long as the matrix A is non-singular. The three equilibrium equations result directly from the market clearing condition in the home and foreign equity markets and in the foreign exchange market. The belief changes \( \mu^H_e, \mu^E_e \) for the international equity fund always appear symmetrically in the term B\( \mu \) but with opposite sign, hence only the relative belief of the international equity investor change \( \mu^H_e - \mu^F_e \) matters for the price determination. The terms \( \lambda_h, \lambda_f \) and \( \lambda_b \) denote ratios of risk aversion multiplied by the respective asset variance. A lower risk aversion or lower price variance implies that belief changes trigger (ceteris paribus) larger demand shifts. We also note that the belief changes of the home and foreign fund only enter the first and second equation, respectively, while belief change of the international equity fund affects all three market clearing conditions simultaneously.

Exogenous belief changes are the only source of price change in our model. But such belief changes are not directly observable. We therefore need assumptions about how to identify them. We resort to the assumption that belief changes are revealed by order flow. Belief change certainly create a motive for each fund to rebalance its portfolio. Theoretically, such rebalancing could occur through a passive limit order submission strategies only. The fund which desire to sell equity would try to maintain the most competitive bid price and reduce its position successively over time as this sell offer is repeatedly executed. In this case the belief shift would not translate into a corresponding (negative) order flow. In practice, however, fund managers typically pursue more active strategies by directly submitting market sell orders. Active order placement tends to accelerate the portfolio rebalancing and avoids front running by other investors. The belief change is then clearly associated with a corresponding (negative) order flow. Recent empirical work on order execution strategies indeed confirm that the likelihood of a market order increases with an investors valuation distance from the spread midpoint (Hollifield et al., 2004). Assuming that funds experiencing belief changes pursue active order placement strategies, we can state the following proposition:

**Proposition 2: Equity Order Flows**
Belief changes $\mu = (\mu_h, \mu_e, \mu_H, \mu_F)$ trigger equity trade initiation resulting in equity market order flow ($OF^H, OF^F$) for the home and foreign, respectively, given by

$$OF^H = k [\mu_h^H + \mu_e^H - \mu_e^F]$$
$$OF^F = k [\mu_e^F + \mu_e^F - \mu_h^H]$$

where the parameters are defined as:

$$k = \frac{1}{\Delta} \times \frac{\lambda_h \lambda_f \lambda_b}{\rho_e \{2 \sigma^2 + (1 + r)^2 \sigma^2_E\}} > 0$$
$$\Delta = \lambda_h \lambda_f \lambda_b + \lambda_h \lambda_f + \lambda_h \lambda_b + \lambda_f \lambda_b$$

Proof: See Appendix.

Order flow in the home and foreign equity market is proportional to the belief change $\mu_h, \mu_e$ of the home and foreign fund, respectively. And in each case order flow depends linearly (with opposite signs) on the relative belief change, $\mu_e^H - \mu_e^F$, of the international equity fund. Hence, as for returns, only the relative belief change is identified though the order flow.

The international equity fund is also assumed to practise active order placement in the foreign exchange market as a corollary to its rebalancing in the two equity markets. The rebalancing in the two equity markets depends on its own relative belief change $\mu_e^H - \mu_e^F$ as well as belief revision of the local funds ($\mu_e^H, \mu_e^F$) which translate into local equity price changes. The resulting foreign exchange order flow is given in proposition 3:

**Proposition 3: Foreign Exchange Order Flows**

The international equity fund initiates foreign exchange transactions in order to finance overseas equity investments. Their overseas investment is determined by their belief change relative to the local equity investors, therefore foreign exchange order flow $OF^E$ follows as

$$OF^E = k [(\mu_h^H - \mu_e^F) - (\mu_e^H - \mu_e^F)] .$$

Proof: See Appendix.

Our identification assumptions of active order placement allow us to restate the structural model in proposition 1 in terms of observable variables only. In particular, belief changes can be substituted by equity order flows and we obtained a reduced form structure summarized as follows:

**Proposition 4: Reduced Form Structure**

The home and foreign equity returns, $R^H$ and $R^F$, are linearly related to the exchange rate return $R^E$ and the home and foreign equity order flows, $OF^H$ and $OF^F$, according to:
\[ R^H = \frac{1}{3} \left[ (1 + \lambda_b) + \lambda_b \left( \frac{\lambda_h - 2 \lambda_f}{\lambda_h \lambda_f} \right) \right] R^E + \frac{1}{3k (1 + r)} (2OF^H + OF^F) \quad (1) \]

\[ R^F = \frac{1}{3} \left[ - (1 + \lambda_b) + \lambda_b \left( \frac{2 \lambda_h - \lambda_f}{\lambda_h \lambda_f} \right) \right] R^E + \frac{1}{3k (1 + r)} (OF^H + 2OF^F) \quad (2) \]

where \( \lambda_h, \lambda_f, \lambda_b > 0 \) and \( k > 0 \) are the previously defined parameters.

Proof: See Appendix.

The reduced form implies that both home and foreign equity returns can be represented as a linear combination of the exchange rate return and both home and foreign equity market order flow. The return equations therefore illustrate market interdependence. Moreover, local equity returns are more sensitive to local order flow than the order flow in the overseas equity market.

The coefficients on exchange rate changes are best interpreted as follows. Consider the possibility that risk aversion towards equities is the same for the home and foreign equity fund. This means that \( \lambda_h = \lambda_f = \lambda \). In this case, the exchange rate coefficient in the home equation is \( \frac{1}{3} \left[ 1 + \lambda_b (1 - 1/\lambda) \right] \) while that in the foreign equation is equal but opposite in sign. Deviations from this symmetry occur when equity risk aversion of the domestic equity fund differs across the two countries. Note that the sum of the two exchange rate coefficients is \( \lambda_b [1/\lambda_f - 1/\lambda_h] \). If risk aversion for the home equity fund is lower than that of the foreign equity fund, this sum is positive and vice-versa. For \( \lambda_h = \lambda_f = \lambda \), we can then express the sum of the two returns as a linear function of the sum of the two equity order flows only,

\[ R^H + R^F = \frac{1}{k (1 + r)} [OF^H + OF^F]. \]

Belief changes by the international equity fund creates off-setting negative and positive order flow and return effects which do not affect the sum of order flow and return. However, this pre-supposed that both equity markets have the same supply elasticities which is not the case under differential risk aversion of the two domestic equity funds. For example, under higher home than foreign risk aversion, \( \lambda_f > \lambda_h \), the sum of the equity returns is increased for a negative exchange rate return (dollar appreciation), \( R^E < 0 \). Intuitively, this corresponds to a case in which the international equity fund has a positive shock \( \mu_e^H - \mu_e^F > 0 \) about home (U.S.) equity and its portfolio rebalancing in favor of home assets appreciates the home currency. Given that the home equity supply is more price elastic than the foreign equity market due to the higher risk aversion of the home fund, price increase in home equity is not fully compensated by the price decrease in for the foreign equity market. This requires an additional adjustment term so that generally

\[ R^H + R^F = \lambda_b \left[ \frac{1}{\lambda_f} \frac{1}{\lambda_h} \right] R^E + \frac{1}{k (1 + r)} [OF^H + OF^F]. \]

Finally, we note that the return difference \( R^H - R^F \) is not fully captured by the corresponding order flow difference, \( OF^H - OF^F \) except in the special case of no belief shock to the international equity fund \( (\mu_e^H = \mu_e^F) \). The term \( \frac{1}{3} \left[ 1 + \lambda_b (1 - 1/\lambda) \right] \) which tends to be positive, corrects for the fact that the order flow difference generally understates (overstate) the return difference for a positive (negative) exchange rate return.
An important advantage of the reduced form is that it can be directly estimated. Both home and foreign returns may be correlated with the exchange rate return. Moreover, both home and foreign order flow influence both the home and foreign equity returns. We highlight the implication of the model that local order flow has twice the impact on local returns as has the non-local equity order flow.

4 Data

An empirical test of the above model would ideally involve many country pairs with developed equity markets. While equity return data is available for almost all countries, the information needed to construct order flow data can only be obtained for a small number of countries. The United States and France are the two largest OECD countries for which individual transaction data on a large part of the domestic equity trading volume is publicly available. We therefore take the U.S. to be the home country and France to be the foreign country. The relevant exchange rate is then the Euro-Dollar rate and we assume that the French equity market is representative of the consolidated euro-zone equity market both in terms of returns and order flow characteristics. Our data spans the five year period from January 1999 to December 2003 and therefore start with the creation of the common European currency.

4.1 U.S. Equity Data

The U.S. order flow data is constructed from the TAQ database with the help of Wharton Research Data Services. We restrict attention to the stocks in the Standard&Poors 100 index and accounted for all their trades on AMEX, NASDAQ and NYSE over the 5 year period, some 2.5 trillion trades in total. All trades are signed as buyer- or seller-initiated depending on whether the executed price was higher or lower than the midpoint between the ask and bid quote respectively.4 Trades executed at the mid-point are not signed. The value of all buy trades in all of the 100 stocks in each day are accumulated to create a single aggregate daily buyer-initiated equity trade series for the U.S. Corresponding series are constructed for the seller-initiated and unsigned trades. The raw aggregate home equity order flow series \( ROF^H \) is then derived as the buyer-initiated series minus the seller-initiated series. Trading volume \( VOL^H \) is derived as the sum of the buyer-initiated, seller-initiated and the unsigned trades series. We define the aggregate normalized order flow series as the ratio of order flow to volume \( OF^H \). The home equity returns series \( R^H \) is the first difference of the log of the New York closing value for the S&P100. It was obtained from Datastream.

4.2 French Equity Data

French order flow data is constructed based on transaction and quote data from Euronext (Données de Marché Historiques). The reference universe consists of all stocks in the French CAC40 index. Again, we use the Lee and Ready (1991) algorithm to sign trades. Analogously to the U.S. data, we obtain daily raw aggregate equity order flow series \( ROF^F \), daily volume series \( VOL^F \) and the daily normalized

---

4 The method used by WRDS restricts itself to quotes that have been in effect for at least five seconds when the trade occurs (see Lee and Ready, 1991).
order flow \((OF^F)\). French aggregate daily equity returns \((RF)\) were defined as difference in the log of the Paris closing price for the CAC40.

Naturally, the home order flow is denominated in U.S. Dollars and the foreign order flow in Euros. We note that the scale of the U.S. market exceeds that of France by almost an order of magnitude. The use of normalized order flow addresses both issues simultaneously as normalized order flow is strictly bounded between -1 and 1. Normalized order flow is also without currency denomination.

### 4.3 Foreign Exchange Data

Daily foreign exchange order flow was obtained directly from Electronic Broking Services (EBS). There are three types of trades in the forex market: customer-dealer trades, direct inter-dealer trades, and brokered inter-dealer trades. Customers are non-financial firms and non-dealers in financial firms (e.g., corporate treasurers, hedge funds, mutual funds, pension funds, proprietary trading desks, etc.). Dealers are market-makers employed in banks worldwide, of which the largest 10 dealing banks account for more than half of the volume in major currencies.

Our data come from the third trade type: brokered inter-dealer trading. There are two main inter-dealer broking systems, EBS and Reuters Dealing 2000-2. Both offer competing central market places through electronic terminals. Estimates by the Bank of England (2001) suggest that electronic brokering was used for 66 percent of all transactions in 2001, up from 30 percent in 1998. Similarly, the Federal Reserve Bank of New York (2001) estimates the market share of electronic trading systems at 71 percent in 2001. Discussions with industry specialists indicate that EBS has a two-thirds market share in the brokered inter-dealer dollar-euro market. Our data set includes the daily value of purchases and sales in the dollar-euro market for first year of our sample, 1999. They are measured in millions of Euros. Unlike the equities data, no algorithm was needed to sign trades (ex post) since this occurs electronically at the moment of execution. Each trading day (weekday) covers the 24 hour period starting at 21.00 GMT. The daily raw foreign exchange order flow series \((ROFE)\) is calculated as the value of buy trades minus the value of sell trades. The daily volume series \((VOLER)\) represents the sum of the value of buy and sell trades and the daily normalized order flow \((OF^E)\) is again defined as the ratio of \(ROFE\) to \(VOLER\). The dollar-euro exchange rate at the New York close was obtained from Datastream. It is defined as the dollar price of euro. The daily foreign exchange return \(RE\) follows as the difference in the log of the exchange rate level.

Table 2 provides descriptive statistics for the variables used in the estimation. These are the quantity variables, \(ROFE, VOL E, OFE, ROFF, VOL F, OFF, ROFH, VOL H, OFH\) and the three returns, \(RF, RH, RE\). For each variable, the table shows the mean, the standard deviation and the first order autocorrelation coefficient.

#### 5 Estimation Results

**5.1 The Reduced Form**

Unlike the structural form in Proposition 1, the reduced form in Proposition 4 can be directly estimated. The unobservable belief changes \(\mu = (\mu^H_e, \mu^E_e, \mu^H_h, \mu^E_f)\) are substituted for order flow variables which proxy
for the belief changes. We note, however, that in the system of two equations, the three parameters $\lambda$ cannot be separately identified. Moreover, the identification rests on the assumption that the equity funds undergoing belief changes implement their portfolio change through active order placement strategies. Since we aggregate over a large number of daily transactions in many different stocks to obtain daily order flow, the proxy character of order flow for belief changes should still be preserved if a certain proportion of portfolio change is achieved through passive limit order submission.

Before we estimate the reduced form system, it's instructive to examine how equity returns are affected by own-order flow. Figures 1 and 2 show scatter diagrams for both the U.S. and France. They show a strong positive correlation. This means that equity index returns are strongly related to aggregate or macroeconomic order flow. But our theory asserts much more. Non-local (or overseas) order flow and the exchange rate return also influence the local equity return. In each equation, the equity return is affected by both home and foreign market order flow. Moreover, local equity returns are more sensitive to local order flow than the order flows into the overseas equity market.

Table 3 displays the estimation results. The upper and lower panels show the results for equations (1) and (2). The first column reports results using Ordinary Least Squares (OLS). The own-order flow is highly significant in both equations with t-statistics of 27.58 and 7.32 in the home and foreign return equation, respectively. The overseas order flow is also highly significant in both equations. As predicted by the theory, the magnitude of the coefficient is less than for own-order flow. The exchange rate return is also significant in both equations. Since both coefficients are negative, we conclude that risk aversion differs between the U.S. and European domestic equity funds. Given a negative sum of the two coefficients, we infer that American domestic equity investors are more risk averse than their European counterparts. We also note that the $R^2$ in both equations is very high. We succeed in explaining almost 60% of daily aggregate U.S. stock returns. Ljung-Box Q tests for both equations show that there is no evidence of autocorrelation up to 5th order.

An obvious criticism against the OLS estimation concerns the endogeneity of exchange rate returns, which implies a simultaneity bias for the coefficients. Finding a suitable instrument for an asset price or its return is generally difficult. However, we know from Evans and Lyons (2002a) that foreign exchange order flow is highly correlated with the exchange rate return. This is confirmed for this particular data set in Hau, Killeen and Moore (2002). We can therefore use foreign exchange order flow as an instrument for the 12 months of 1999. Estimation proceeds by Two Stage Least Squares (2SLS). Columns 2 and 3 give both the OLS and the 2SLS estimates for the year 1999. Comparing the two sets of estimates for equation 1, it is hard to find any difference between the OLS and 2SLS cases for the first year of the sample. This is formally confirmed by the result of the Hausmann specification test in the upper panel. For the foreign returns equation, the only estimate that appears to change is the exchange rate returns coefficient. Nevertheless, it is still negative and significant and again the Hausmann specification test rejects the endogeneity of the exchange rate, at least for this instrument. We conclude that the OLS estimates for the full sample are confirmed by the instrumental variable procedure.

---

5 Our theory is actually quite specific. It indicates that the own-order flow coefficient should be precisely twice the overseas order flow coefficient. Statistically, this is rejected for both equations.

6 The exogeneity of aggregate daily order flow is exhaustively discussed in Killeen, Lyons and Moore (forthcoming, 2005)

7 The data on foreign exchange order flow is available only for the first year of the sample.

8 We also estimated the two equations as a system using Seemingly Unrelated Regressions (SUR). It makes almost no
Finally, we examine the intertemporal robustness of the return equations. The last line in each of the panels of Table 3 reports the Chow tests on the parameters between 1999 and the rest of the sample. In the upper panel, the estimated coefficients on both the exchange return and foreign order flow appear to be stable. However, the price impact of home equity order flow is smaller for 1999 than for the whole sample. However, it is still large, positive and significant. A formal Chow test confirms the absence of intertemporal instability for the U.S. returns equation. For the foreign returns equation, the exchange rate return coefficient is also stable, but both order flow coefficients are smaller in 1999. The upward trend for the order flow coefficients is confirmed by the rejection of the stability assumption underlying the Chow test. Despite this unfavorable statistical result, it is difficult to argue that the 1999 sub-period displays any economically significant difference relative to the whole sample period.

5.2 Deviations from Uncovered Equity Parity

The equations in proposition 4 can be easily transformed into an expression for the analogue to uncovered interest parity for equities, namely uncovered equity returns parity (Derviz (2004), Hau and Rey (2003)). The uncovered equity parity terms \( R_H - R_F - R_E \) captures the excess return (in home currency terms) of a simultaneous long and short position in home and foreign equity, respectively. The model predicts how deviations from uncovered equity market relate to exchange rate returns itself and order flow differences across both equity markets. Formally,

\[
R_H - R_F - R_E = \frac{1}{3} \left[ -1 + \lambda_b \left\{ 2 - \frac{(\lambda_h + \lambda_f)}{\lambda_h \lambda_f} \right\} \right] R_E + \frac{1}{3k(1+r)} [OF_H - OF_F] 
\]

The exchange rate return appears on the right hand side and its sign is ambiguous. The results of estimating the above equation are displayed in the first column of Table 4. The striking feature is that the \( R^2 \) is high at 40 percent. All three explanatory variables are highly significant and the equity order flow variables both have the sign predicted by theory.

Theories of uncovered interest parity typically find it difficult to explain why the interest differential \( i^H - i^F \) is uncorrelated with the exchange rate changes. In fact risk premia defined as the deviations \( i^H - i^F - R_E \) from uncovered interest parity are very difficult to explain empirically. Our model provides a simple closed form characterization of the time-varying risk premium which mark deviations from uncovered equity parity.

Equation (3) can be restated by substituting for the exchange rate return on the right hand side. We can express the exchange rate return as

\[
R^E = \rho_b(1 + r)\sigma^2_E \left[ \frac{\mu^H - \mu^F}{\sigma^2_E} \right] \left[ k \left( \mu^H - \mu^F \right) - \left( \mu^H - \mu^F \right) \right],
\]

and using proposition 3 we obtain directly

\[
R^E = \rho_b(1 + r)\sigma^2_E \left[ OF^E \right].
\]

The exchange rate returns is directly proportional to foreign exchange order flow \( OF^E \). We can therefore give a structural interpretation of the Evans and Lyons (2002a) expression for the price impact of order flow. The price or return impact is governed by the parameter \( \rho_b(1 + r)\sigma^2_E \), which depends on the difference to neither the estimated coefficients nor the standard errors.
volatility of the exchange rate returns and risk aversion \( \rho \) of the international bond funds which provide the liquidity in the foreign exchange market. Substituting in for the exchange rate return on the right hand side of equation (3), we obtain

\[
R^H - R^F - R^E = \frac{1}{3} \left[ \rho_b (1 + r) \sigma^2_E \right] \left[ -1 + \lambda_b \left\{ 2 - \frac{(\lambda_h + \lambda_f)}{\lambda_h \lambda_f} \right\} \right] OF^E + \frac{1}{3k(1+r)} \left[ OF^H - OF^F \right]. \tag{4}
\]

Deviations from uncovered equity returns parity can be explained by three order flows, namely foreign exchange order flow with a negative sign, home equity order flow with a positive sign and foreign equity order flow with equal but opposite negative sign. The results are shown in Table 4. The \( R^2 \) is almost 40\%, all variables are very significant and have the correct sign.\(^9\)

We conclude that order flow in the three markets has considerable explanatory power for time varying risk premia. The empirical fit of the model surpasses by far previous attempts to explain similar time varying risk premia for uncovered interest parity. On the other hand, our framework related the order flows directly to heterogenous belief changes and therefore allows for a coherent interpretation of these order flows instead of taking them as exogenous as the microstructure literature does.

### 6 Conclusion

We presented a model in which equity order flow is the expression of heterogenous belief shifts by different investors. The multimarket setting provides not only for enough observable prices and order flows to identify heterogenous belief shifts, but it also implies testable restrictions for international market interdependence. We derived a closed-form solution for equity returns in both equity markets, which relates equity returns to the exchange rate and to order flows in both the local and the overseas market.

We confront the model with 5 years of daily U.S. and French equity data. The respective daily order flows for the S&P100 and the CAC40 index are constructed based the aggregation of approximately 3 trillion individual equity transactions. We find that an extraordinarily high percentage of aggregate equity return variation is explained jointly by exchange rate returns and macroeconomic order flows. Our model can explain approximately 60 percent of the daily variation in the S&P100 return and 40 percent of the CAC40 return fluctuations. As predicted by theory, both returns are strongly influenced not only by own market order flow, but also by the order flow in the overseas market. Finally, we show that time varying risk premia, defined as the deviations from uncovered equity parity, are also well explained by the model. In summary, heterogenous belief changes as identified by order flows appears to provide a promising paradigm for future research on equity index movements, exchange rates and international financial market interdependence.

---

\(^9\) The only feature which contradicts the theory is that the coefficient on French equity order flow is lower in absolute value than that on U.S. equity order flow. Nevertheless the results are encouraging.
References

Appendix

Proposition 1: Returns and Heterogenous Beliefs

The four investment funds $i = e, b, h, f$ pursue investment objectives which maximize a CARA objective function. For normally distributed payoff this simplifies to a utility function in conditional mean and conditional variance of the payoff. For price changes $\Delta P_1$ and $\Delta P_2$ in two assets and corresponding asset holdings $x_1$ and $x_2$ the payoff is given by $\Delta \Pi = x_1 \Delta P_1 + x_2 \Delta P_2$. For a budget constraint $x_1 P_1 + x_2 P_2 = 0$, we obtain $\Delta \Pi = x_1 \left[ \Delta P_1 - \frac{P_1}{P_2} \Delta P_2 \right]$ and the optimal asset demand can be stated as

$$x_1 = \frac{\mathcal{E}(\Delta P_1 - \frac{P_1}{P_2} \Delta P_2 \mid I)}{\rho \text{Var}(\Delta P_1 - \frac{P_1}{P_2} \Delta P_2 \mid I)},$$

where $\mathcal{E}(\cdot \mid I)$ denotes conditional expectation, $\text{Var}(\cdot \mid I)$ the conditional variance and $\rho$ the coefficient of absolute risk aversion.

Let $V^H, V^F$ and $V^E$ denote the liquidation value of the home equity, the foreign equity and the foreign currency respectively. The corresponding equilibrium prices are $P^H, P^F$ and $E$. For the home and foreign equity fund, the second asset is a bond with a unit price $(P_2 = 1)$ and a return $\Delta P_2 = r$. Hence, their optimal asset demands are given by

$$x^H_h = \frac{\mathcal{E}_f[V^H - P^H - P^H r^H \mid I]}{\rho_h \text{Var}_h(V^H \mid I)} = \frac{V^H + \mu^H - (1 + r^H) P^H}{\rho_h \sigma^2},$$

$$x^F_f = \frac{\mathcal{E}_f[V^F - P^F - P^F r^F \mid I]}{\rho_f \text{Var}_f(V^F \mid I)} = \frac{V^F + \mu^F - (1 + r^F) P^F}{\rho_f \sigma^2}.$$

For the international equity fund the payoff is given by

$$\Delta \Pi_e = x_1 \left[ \Delta P_1 - \frac{P_1}{P_2} \Delta P_2 \right] = x^H_e \left[ V^H - P^H - \frac{P^H}{E P^F} (V^E V^F - E P^F) \right].$$

For steady state values $\mathcal{V}^H, \mathcal{P}^H, \mathcal{V}^E, \mathcal{E}, \mathcal{V}^F, \mathcal{P}^F$, we can linearize the excess return on home equity as

$$V^H - P^H - \frac{P^H}{E P^F} (V^E V^F - E P^F) =$$

$$(V^H - \mathcal{V}^H) - (P^H - \mathcal{P}^H) - \frac{\mathcal{V}^E \mathcal{V}^F - \mathcal{E} \mathcal{P}^F}{\mathcal{E} \mathcal{P}^F} (P^H - \mathcal{P}^H) + \frac{\mathcal{V}^E \mathcal{V}^F \mathcal{P}^H}{\mathcal{E} (\mathcal{P}^F)^2} (P^F - \mathcal{P}^F) +$$

$$+ \frac{\mathcal{V}^E \mathcal{V}^F \mathcal{P}^H}{(\mathcal{E})^2 \mathcal{P}^F} (E - \mathcal{E}) - \frac{\mathcal{V}^E \mathcal{P}^H}{\mathcal{P}^F} (V^E - \mathcal{V}^E) - \frac{\mathcal{V}^E \mathcal{P}^H}{\mathcal{E} \mathcal{P}^F} (V^F - \mathcal{V}^F) =$$

$$(V^H - \mathcal{V}^H) - \frac{\mathcal{V}^E}{\mathcal{V}^F} (P^H - \mathcal{P}^H) + \frac{\mathcal{V}^E}{\mathcal{P}^F} (P^F - \mathcal{P}^F) + \mathcal{V}^F (E - 1) - \mathcal{V}^F (V^E - 1) - (V^F - \mathcal{V}^F).$$

The final equality is obtained (for reasons of model symmetry\(^{10}\)) by using $\mathcal{V}^H = \mathcal{V}^F, \mathcal{V}^E = \mathcal{E} = 1, \mathcal{P}^H = \mathcal{P}^F$. For the international equity fund the optimal asset demand follows as

\(^{10}\)There is one asymmetry in the model. This is the choice of currency in which the international fund is denominated. However, this has a second order impact on the model. We abstract from this.
\[ x^H_e = \frac{\mathcal{E}_I \left[ (V^H - V^H) - (V^F - V^F) - \frac{\sigma^F}{\rho_e}(P^H - P^H) + \frac{\sigma^F}{\rho_e}(P^F - P^F) + \sigma^F (E - 1) - \sigma^F (V^E - 1) \right]}{\rho_e \text{Var}_e \left[ (V^H - V^H) - \frac{\sigma^H}{(1 + r)}(E - V^E) \right]} \]

\[ = \frac{\mu_e^H - \mu_e^F - \frac{\sigma^H}{\rho_e}(P^H - P^H) + \frac{\sigma^H}{\rho_e}(P^F - P^F) + \sigma^H (E - 1)}{\rho_e \left\{ 2\sigma^2 + \left(\frac{\sigma^H}{\rho_e} \right)^2 \sigma^2_E \right\}} \]

For the international bond fund, the payoff is given by

\[ \Delta \Pi_b = x^H_b \left[ r^H - \frac{1}{E} (V^E(1 + r^F) - E) \right] \approx x^H_b (1 + r)(E - V^E), \]

where bond prices are normalized to 1 and \( r^H = r^F = r \). The optimal demand of the international bond investor follows as

\[ x^H_b = \frac{\mathcal{E}_b \left[ (1 + r)(E - V^E) \right]}{\rho_b \text{Var}_b \left[ (1 + r)(E - V^E) \right]} = \frac{E - 1}{\rho_b (1 + r) \sigma^2_E}. \]

The steady state (marked by upper bars) follows for \( \mu^H_e = \mu^E_e = \mu^H_b = \mu^F_b = 0 \). Then market clearing implies

\[ 0 = \frac{\sigma^F (E - 1)}{\rho_e \left\{ 2\sigma^2 + \left(\frac{\sigma^H}{\rho_e} \right)^2 \sigma^2_E \right\}} + \frac{\sigma^H (E - 1)}{\rho_b \sigma^2_E}. \]

Inspection of the above equation reveals that \( \sigma^H V^H = (1 + r)P^H, \sigma^F V^F = (1 + r)P^F \) and \( E = 1 \) is a solution. This implies \( \sigma^H = \sigma^F = 0 \) and from the budget constraint of the international equity fund, \( x^H_e P^H + x^E_e P^F = 0 \), we get \( \sigma^H = \sigma^F = 0 \). Therefore \( \sigma^F = (1 + r)P^F \). We can further simplify by setting \( \sigma^H = \sigma^F = 1 \). Finally, we can also derive a simple expression for the international equity fund’s foreign equity demand, \( x^F_e \). From its budget constraint, we get through linearization around the steady state holdings \( \sigma^H_e = \sigma^E_e = 0 \) directly

\[ x^F_e = -x^H_e \frac{\sigma^H_e}{\sigma^F} = -x^H_e. \]

Next we solve for the equilibrium prices \( P^H, P^F \) and \( E \) under general belief changes \( \mu = (\mu^H_e, \mu^E_e, \mu^H_b, \mu^F_b) \).

Market clearing in the two equity markets implies

\[ 0 = \frac{\mu^H_e - \mu^F_e - (1 + r)(P^H - 1) + (1 + r)(P^F - 1) + (1 + r)(E - 1)}{\rho_e \left\{ 2\sigma^2 + (1 + r)^2 \sigma^2_E \right\}} + \frac{\sigma^H_e - (1 + r)P^H}{\rho_h \sigma^2_E}. \]

Market clearing in the currency market occurs between the two international funds and yields

\[ 0 = x^H_e + x^B_e = \frac{\mu^H_e - \mu^F_e - (1 + r)(P^H - 1) + (1 + r)(P^F - 1) + (1 + r)(E - 1)}{\rho_e \left\{ 2\sigma^2 + (1 + r)^2 \sigma^2_E \right\}} + \frac{E - 1}{\rho_b (1 + r) \sigma^2_E}. \]
Define strictly positive parameters
\[
\lambda_h = \frac{\rho_c}{\rho_h \sigma^2} \left[ 2\sigma^2 + (1 + r)^2 \sigma_E^2 \right], \quad \lambda_f = \frac{\rho_c}{\rho_f \sigma^2} \left[ 2\sigma^2 + (1 + r)^2 \sigma_E^2 \right], \quad \lambda_b = \frac{\rho_c}{\rho_b (1 + r)^2 \sigma_E^2} \left[ 2\sigma^2 + (1 + r)^2 \sigma_E^2 \right].
\]

We obtain a linear system of three equations in 3 endogenous return variable given by \( R^H = P^H - 1 \), \( R^F = P^F - 1 \) and \( R^E = E - 1 \),
\[
\begin{bmatrix}
    (1 + \lambda_h) & -1 & -1 \\
    -1 & (1 + \lambda_f) & 1 \\
    -1 & 1 & (1 + \lambda_b)
\end{bmatrix}
\begin{bmatrix}
    R^H \\
    R^F \\
    R^E
\end{bmatrix}
= \frac{1}{1 + \rho_f} \begin{bmatrix}
    \mu_e^H - \mu_e^F + \mu_h^H \lambda_h \\
    \mu_e^F - \mu_h^H + \mu_f^F \lambda_f \\
    \mu_e^F - \mu_e^H
\end{bmatrix}.
\]

The return vector \( \mathbf{R} = (R^H, R^F, R^E) \) can then be expressed linearly in terms of belief changes \( \mathbf{\mu} = (\mu_e^H, \mu_e^F, \mu_h^H, \mu_f^F) \) as \( \mathbf{R} = \mathbf{A}^{-1} \mathbf{B} \mathbf{\mu} \). This proves proposition 1.

**Proposition 2: Equity Order Flow**

Order flow as signed transaction volume is directly related to the initiated position change of each trader. We assume that the trader experiencing the belief change is also the one who initiates the transactions. Order flow in the home equity market if given as the sum \( OF^H = OF^H_h + OF^H_f \) of the order flow by the home and international fund. Similarly we have \( OF^F = OF^F_f + OF^F_e \). The order flow of each fund is given for price functions \( P^H (\cdot) \), \( P^F (\cdot) \), and \( E (\cdot) \) by
\[
\begin{align*}
OF^H_h &= \frac{\mu_e^H - (1 + r) (P^H (\mu_e^H) - 1)}{\rho_h \sigma^2} \\
OF^F_f &= \frac{-(1 + r) (P^F (\mu_e^F) - 1)}{\rho_f \sigma^2} \\
OF^H_e &= \frac{\mu_e^H - \mu_e^F - (1 + r) (P^H (\mu_e^H - \mu_e^F) - 1) + (1 + r) (P^F (\mu_e^H - \mu_e^F) - 1) + (1 + r) (E (\mu_e^H - \mu_e^F) - 1)}{\rho_e \left[ 2\sigma^2 + (1 + r)^2 \sigma_E^2 \right]} \\
OF^F_e &= \frac{-\mu_e^H - \mu_e^F - (1 + r) (P^H (\mu_e^H - \mu_e^F) - 1) + (1 + r) (P^F (\mu_e^H - \mu_e^F) - 1) + (1 + r) (E (\mu_e^H - \mu_e^F) - 1)}{\rho_e \left[ 2\sigma^2 + (1 + r)^2 \sigma_E^2 \right]}
\end{align*}
\]

The equilibrium prices are given by
\[
\begin{align*}
P^H - 1 &= \frac{\lambda_f \lambda e}{(1 + r) \Delta} (\mu_e^H - \mu_e^F) + \frac{\lambda_h \lambda e}{(1 + r) \Delta} \mu_h^H + \frac{\lambda_e \lambda_f}{(1 + r) \Delta} \mu_f^F \\
P^F - 1 &= \frac{-\lambda_h \lambda e}{(1 + r) \Delta} (\mu_e^H - \mu_e^F) + \frac{\lambda_h \lambda e}{(1 + r) \Delta} \mu_h^H + \frac{\lambda_f \lambda e}{(1 + r) \Delta} \mu_f^F \\
E - 1 &= \frac{-\lambda_f \lambda h}{(1 + r) \Delta} (\mu_h^H - \mu_h^F) + \frac{\lambda_f \lambda h}{(1 + r) \Delta} \mu_h^H - \mu_f^F
\end{align*}
\]

and price changes induced by the respective belief changes can be observed as

32
We obtain the equity order flows as

\[ \begin{align*}
OF^H &= k [\mu^H - \mu^e] \\
OF^F &= k [\mu^F - \mu^H - \mu^e]
\end{align*} \]

where we defined

\[ \begin{align*}
k &= \frac{1}{\Delta} \times \frac{\lambda_h \lambda_f \lambda_b}{\rho_e \left\{ 2\sigma^2 + (1 + r)^2 \sigma^2 \right\}} > 0 \\
\Delta &= \lambda_h \lambda_f \lambda_b + \lambda_h \lambda_f + \lambda_h \lambda_b + \lambda_f \lambda_b.
\end{align*} \]

Proposition 3: FX Order Flow

The international bond fund is the liquidity provider in the FX market. It does not experience any belief changes. Order flow in the FX market, \( OF^E \), therefore arises from the market orders of the international equity fund. Those comprise two components. First, there are the market orders due to its own belief changes, \( OF^F_e = -OF^H_e \). Second, the belief changes of the home and foreign funds lead to market orders absorbed by the international fund, which passes those in turn into the FX market as market orders. Those order flows are given by \( OF^H_e - OF^F_f \). Hence

\[ OF^E = OF^F_e + OF^H_e - OF^F_f = k(\mu^H_e - \mu^F) - k(\mu^e - \mu^F) \].

Proposition 4: Reduced Form Structure

The above system of equations (from proposition 1) can be rewritten as

\[ \frac{(1 + \lambda_h)\lambda_f - \lambda_f}{(1 + \lambda_f)\lambda_h - \lambda_h} \begin{bmatrix} R^H \\ R^F \\ R^E \end{bmatrix} = \frac{1}{1 + r} \begin{bmatrix} (\mu^H_e - \mu^F)\lambda_f + \mu^H_h \lambda_f \\ (\mu^F_e - \mu^H)\lambda_h + \mu^F_F \lambda_f \lambda_h \\ \mu^F_e - \mu^H_e \end{bmatrix} \]

Adding the first two equations yields

\[ \frac{(1 + \lambda_h)\lambda_f - \lambda_h}{1} \begin{bmatrix} R^H \\ R^F \\ R^E \end{bmatrix} = \frac{1}{1 + r} \begin{bmatrix} (\mu^H_e - \mu^F)(\lambda_f - \lambda_h) + (\mu^H_e + \mu^F)\lambda_h \lambda_f \\ \mu^F_e - \mu^H_e \end{bmatrix} \]
and adding \((\lambda_f - \lambda_h)\) times the last equation gives

\[
\begin{bmatrix}
\lambda_h \lambda_f & \lambda_f \lambda_h & (\lambda_f - \lambda_h) \lambda_h \\
-1 & 1 & (1 + \lambda_h)
\end{bmatrix}
\begin{bmatrix}
R^H \\
R^F \\
R^E
\end{bmatrix}
= \frac{1}{1 + \rho} \begin{bmatrix}
(\mu_h^H + \mu_f^F) \lambda_h \lambda_f \\
\mu_h^F - \mu_e^F
\end{bmatrix}.
\]

Finally, dividing the first equation by \(\lambda_h \lambda_f\), we obtain

\[
\begin{bmatrix}
1 & 1 & (\lambda_f - \lambda_h) \lambda_h \\
1 & -1 & -(1 + \lambda_h)
\end{bmatrix}
\begin{bmatrix}
R^H \\
R^F \\
R^E
\end{bmatrix}
= \frac{1}{1 + \rho} \begin{bmatrix}
\mu_h^H + \mu_f^F \\
\mu_h^F - \mu_e^F
\end{bmatrix}.
\]

The order flow definitions allow us to rewrite

\[
OF^H + OF^F = k \left[ \mu_h^H + \mu_f^F \right]
\]

\[
OF^H - OF^F = k \left[ (\mu_h^H - \mu_f^F) + 2 (\mu_e^H - \mu_e^F) \right].
\]

Note that the exchange rate return can be expressed as

\[
R^E = \frac{-\lambda_f \lambda_h}{(1 + \rho) \Delta} (\mu_e^H - \mu_e^F) + \frac{\lambda_h \lambda_f}{(1 + \rho) \Delta} (\mu_h^H - \mu_f^F)
\]
or

\[
\frac{1}{\rho (1 + \rho) \sigma^2_E} R^E = -k (\mu_e^H - \mu_e^F) + k(\mu_h^H - \mu_f^F)
\]

\[
= -3k (\mu_e^H - \mu_e^F) + (OF^H - OF^F)
\]
or

\[
\mu_h^H - \mu_e^F = \frac{1}{3k} (OF^H - OF^F) - \frac{1}{3k(1 + \rho) \sigma^2_E} R^E.
\]

Substitution then implies

\[
\begin{bmatrix}
1 & 1 & \frac{\lambda_e (\lambda_f - \lambda_h)}{\lambda_h \lambda_f} \\
1 & -1 & -(1 + \lambda_h)
\end{bmatrix}
\begin{bmatrix}
R^H \\
R^F \\
R^E
\end{bmatrix}
= \left[ \frac{1}{3k(1 + \rho)} (OF^H + OF^F) \right] \left[ \frac{1}{3k(1 + \rho)} (OF^H - OF^F) - \frac{1}{3k(1 + \rho) \sigma^2_E} R^E \right].
\]

Adding the two equations implies the following expression for home returns

\[
R^H = \frac{1}{3} \left[ (1 + \lambda_h) \lambda_h \lambda_f \frac{2 \lambda_f - \lambda_f}{\lambda_h \lambda_f} \right] R^E + \frac{1}{3k(1 + \rho)} (2OF^H + OF^F)
\]

and subtracting gives

\[
R^F = \frac{1}{3} \left[ -(1 + \lambda_h) \lambda_h \lambda_f \frac{2 \lambda_h - \lambda_f}{\lambda_h \lambda_f} \right] R^E + \frac{1}{3k(1 + \rho)} (OF^H + 2OF^F)
\]

where we used

\[
(1 + \lambda_h) - \frac{1}{3k \rho (1 + \rho) \sigma^2_E} = (1 + \lambda_h) - \frac{1}{3} \Delta \lambda_h \lambda_f
\]

\[
= (1 + \lambda_h) - \frac{1}{3} \left\{ (1 + \lambda_h) + \lambda_e \frac{(\lambda_h + \lambda_f)}{\lambda_h \lambda_f} \right\}
\]

\[
= \frac{2}{3} (1 + \lambda_h) - \frac{1}{3} \lambda_e \frac{(\lambda_h + \lambda_f)}{\lambda_h \lambda_f}.
\]
Table 1: Investment Opportunities

Represented are the investment opportunities for the four funds $i = e, b, h, f$ in the four markets (Yes/No) and the notation for their respective belief shocks in the equity market.

Table 2: Summary Statistics

For five year period 01/1999 to 12/2003 we report for the U.S. (H) and French (F) equity market, as well as dollar/euro foreign exchange market (E) the mean, standard deviation (S.D.), and first-order autocorrelation (AR(1)) of the daily stock market returns, $R^H$ (S&P100) and $R^F$ (CAC40), the daily dollar-euro exchange rate return ($R^E$), the raw daily order flows ($ROF$), daily trade volume ($VOL$), and the normalized daily order flow ($OF$) defined as the ratio of raw order flow and volume. The daily exchange rate order flow is available only for 12 months from 01/1999 to 12/1999.

Table 3: Reduced Form Estimates

U.S. and French stock returns, $R^H$ (S&P100) and $R^F$ (CAC40), respectively, are each regressed on the daily dollar-euro exchange rate return $R^E$ as well as daily U.S. ($OF^H$) and French ($OF^F$) equity order flow. The equations are estimated using ordinary least squares for the whole sample (OLS, 01/1999-12/2003), ordinary least squares for 1999 only (OLS, 01/1999-12/1999), and two stage least squares for 1999 using foreign exchange order flow as an instrument for exchange rate returns (2SLS, 01/1999-12/1999). T-tests are in parantheses. They are calculated using White’s heteroscedasticity robust standard errors.

**Equation 1: U.S. Equity Returns**

\[
R^H = \frac{1}{3} \left[ (1 + \lambda_b) + \lambda_b \left( \frac{\lambda_b - 2\lambda_f}{\lambda_b \lambda_f} \right) \right] R^E + \frac{1}{3k(1+r)}(2OF^H + OF^F)
\]

</table>
Table 3: Uncovered Equity Returns Parity

In equation 1, the deviation between U.S. and French equity returns, expressed in US dollars, \( R^H - R^F - R^E \) is regressed on daily dollar-euro exchange rate returns \( R^E \) as well as daily U.S. (\( OF^H \)) and French (\( OF^F \)) equity order flow. The equation is estimated using ordinary least squares for the whole sample (01/1999-12/2003). In equation 2, the same dependant variable is regressed on daily dollar-euro order flow \( OF^E \) and again on daily U.S. (\( OF^H \)) and French (\( OF^F \)) equity order flow for the first year of the sample (01/1999-12/1999). T-tests are in parantheses. They are calculated using Newey West robust standard errors, which also correct for autocorrelation.

Equation 3: Exchange Rate Return as Independent Variable

\[
R^H - R^F - R^E = \frac{1}{3} \left[ -1 + \lambda_b \left\{ 2 \left( \frac{\lambda_h + \lambda_f}{\lambda_h \lambda_f} \right) \right\} \right] R^E + \frac{1}{\sqrt{(1+r)}} [OF^H - OF^F]
\]

Equation 4: Exchange Rate Order Flows as Independent Variable

\[
R^H - R^F - R^E = \frac{1}{3} \left[ \rho_b (1+r) \sigma^2_E \right] \left[ -1 + \lambda_b \left\{ 2 \left( \frac{\lambda_h + \lambda_f}{\lambda_h \lambda_f} \right) \right\} \right] OF^E + \frac{1}{\sqrt{(1+r)}} [OF^H - OF^F]
\]
Figure 1: Plotted are daily returns in the S&P100 index against normalized daily order flow into the U.S. equity market for the five year period 1999 to 2003.
Figure 2: Plotted are daily returns in the CAC40 index against normalized daily order flow into the French equity market for the five year period 1999 to 2003.
Figure 3: Plotted are daily returns in the Dollar/Euro exchange rate against normalized daily order flow in the EBS trading system for the year 1999.
